At a meeting of the Section of Medicine of the Royal Academy of Medicine in Ireland in May, with the president, Dr P T O'Farrell in the chair, Dr M I Drury showed one of a series of cases of pulmonary tuberculosis treated by artificial pneumoperitoneum. The patient, 32 years old, had bilateral pulmonary tuberculosis, maximal on the right side, when admitted to Rialto Hospital in June 1941. Up to May, 1943 he had been treated by rest in bed, after which date he was given two courses of sanocrysin totalling 4.35 g., with continuation of strict bed rest. In February, 1944, right phrenic crush, done by Mr T C J O'Connell, caused elevation of the right dome of the diaphragm by 1½ in. Pneumoperitoneum induced shortly afterwards raised this cupola by a further 2 in., as well as raising the left cupola 1½ in. The patient's general condition had improved, sputum had fallen from 4 to 1½ oz a day, blood sedimentation rate was almost normal, and once for the first time in three years his sputum had been negative for tubercle bacilli. Dr Drury also showed x-ray films of a case of bilateral pulmonary tuberculosis in which both hemidiaphragms were raised by 2½ in. by artificial pneumoperitoneum, although no phrenic interruption had been carried out. Dr E T Freeman considered the indication for pneumoperitoneum was adhesions between the lung and the diaphragm.

A number of postgraduate qualifications are already registrable in the *Medical Register* including the M.D. and M.S. or its equivalent of all universities, the higher diplomas in medicine and surgery granted by the licensing corporations, and the diplomas and degrees in public health. Diplomas in branches or subdivisions of medicine and surgery granted by universities or corporations are not registrable.

Correspondence

Air Disinfection

SIR.—The paper by Prof. Mudd of the University of Pennsylvania and your leader on the subject of air disinfection (July 15, pp. 67 and 82) contain much of interest to us, but in the section dealing with the progress made in the use of germicidal aerosols there are notable omissions of relatively early work. Portslade laboratories has been occupied almost exclusively with the study of this question since 1937, but it would appear that many observations emanating from other laboratories as well as our own are comparatively unknown.

Rightly or wrongly we have been in the habit of considering Bechhold (1935) as the originator of the aerosol theory, although he did not, to our knowledge, coin the word "aerosol." "Exhaustive experiments unexpectedly show that the action is not caused by gaseous state, but principally by the action of finely distributed material as mist or smoke."

For some 40 years Trillat has been publishing results of his work on the behaviour of air-borne bacteria in various environmental conditions. These studies culminated in his infecting animals with air-borne influenza virus and various bacteria, and preventing infection by means of atomized germicides (1939). We came to the same conclusion as Trillat, a conclusion expressed in Bechhold's own words: "Exceptional effects may be obtained with extremely small quantities, mainly due to their low vapour pressure, the vapour concentration being insufficient to act."

Investigations during the last few years by others and ourselves have led us to conclude that we were wrong in viewing the action of lowly volatile substances as being substantially due to direct contact of the germicide and bacterial particle—a view which was always unacceptable on mathematical grounds to our colleagues Finn and Powell, unless accessory factors were involved. We accept, provisionally, the vapour theory as an explanation for the mechanism of action of lowly as well as highly volatile germicides. It was assumed, and subsequently demonstrated experimentally in the early days of our work, that the latter acted in the vapour phase, being, of necessity, non-existent as mists unless used in amounts sufficient to saturate.

It may be pointed out that considerable work has been done by Trillat, and at Portslade (1940a), on the action of hypochlorites on salivary organisms, and the great importance of relative humidity on the activity of these and other types of germicides formed for us a special study (1941). Trillat also has for years consistently emphasized the relative insusceptibility to aerial germicides of desiccated bacteria, which, however, he considered of less danger than those freshly emitted from an infected individual. Again, the observation that propylene glycol is active on air-borne bacteria was, to the best of our knowledge, first made in these laboratories (1940b) and not in America. We felt, however, at the time, that the amount required in order to attain the arbitrary standard of kill we had set ourselves was likely to be prohibitive. The glycol was found to have an activity of the order of 1000:1 on phenol, and this, in the main, has been confirmed in several excellent papers by Robertson and his colleagues.

As regards vapour pressure in relation to bactericidal activity, propylene, diethylene, and probably the other glycols, in our experience, fall into line with the phenols (1944). The results are superior with the highly volatile if the percentage saturation be high, but with the lowly volatile if the percentage saturation be low. At intermediate degrees of saturation results tend to be similar—i.e., an equal bactericidal activity when the amount of germicide atomized is proportional to the amount required to saturate at 20° C. (our working temperature). For instance, as regards the amount of propylene glycol and hexyl resorcinol required to saturate, the ratio is about 500:1, while the proportions in our original mixture were only 9:1. When a large amount of the mixture is used, as was presumably done by Robertson, one would not expect the results obtained with the glycol alone to be improved upon, while when a small amount was used, in our case mostly 10 mg./m.³, the presence

of H.R. made a negative result into a strong positive. Even in the latter example there is more than sufficient H.R. to saturate, but only about 1/40th that of the glycol—too low a degree of saturation of any glycol or phenol tested here to give an appreciable kill of salivary organisms.

Thus it appears that, as in the test-tube so in the air, the solubility of the germicide in the medium in which it is operating has an important bearing on bactericidal capacity. Among 20 phenols tested here no member very soluble in water has a high degree of activity in the test-tube, and no member very soluble in the air has a high activity as an aerosol. A low solubility, however, in either medium does not in every instance correspond to a high bactericidal activity in the particular medium. The possible reasons for this cannot be entered into here; they are both numerous and complex. Among other aspects, molecular potency, rate of generation and decay of the germicide mists and vapours, absorption in relation to adsorption, and the competition of the living organism compared with the "dead" surround, etc., for the germicide are, perhaps, not the least important.

The concluding remarks in your leader prompt us to state that certainly, so far as we are concerned, disinfection with avoidance of sterilization has been and is the main objective, and we believe that the same applies to most workers in this field. Furthermore, our ideal is attenuation and not killing of the pathogenic organisms. Already Trillat (1932) had shown that vaccination of his experimental animals could be accomplished by inhalation of organisms treated with germicidal aerosols. In connexion with proposed therapeutic or prophylactic measures, the wise advocate never neglects the fundamental biological law that the depriving of an organ of facilities for performing its natural function may ultimately lead to its inability to perform this function efficiently when occasion arises for it to do so.

It remains for future experiments to show whether attenuation will be attained more satisfactorily by utilizing suitable amounts of a slow "killer" (H.R.) than by utilizing a fast "killer" (P. glycol).—We are, etc.,

Fulminating Diphtheria

SIR.—Under this heading (July 15, p. 78) Dr. Strong records a fatal case of hypertoxic diphtheria in a fully inoculated child. Although the combination of factors in this case was unusual, similar cases of hypertoxic or malignant diphtheria are unfortunately not rare in areas which are heavily infected by *C. diphtheriae gravis*. It is not yet generally realized that this organism may sometimes elaborate a lethal dose of toxin within a matter of hours after the onset of symptoms, and that because of this a fatal issue may occur in spite of antitoxin therapy at an apparently early clinical stage.

The presence of "bull neck" with tonsillar enlargement and nasal discharge suggests that the patient suffered a severe nasopharyngeal attack. The fauces then would also show the peculiar translucent oedema which precedes the formation of membrane and which is often accompanied by post-nasal obstruction. Feter oris and absence of pain are also usual. In Gateshead, after eight years' experience of this type of invasive diphtheria in epidemic form, the presence of "bull neck" is regarded as an indication for massive dosage of antitoxin by the quickest possible route. Even so, doses of 100,000 units given on the second day of the illness have not always saved the patients. In these cases, too, further spread of membrane may be observed over a day or two after treatment by antitoxin, and the subsequent disintegration of the membrane takes a period of a week, or even longer. In Dr. Strong's abbreviated clinical report there is no indication of a spread of membrane to the larynx, and one wonders if tracheotomy was performed for that reason.

Surely the nasal contact carrier, who had recovered from a previous attack of diphtheria and was harmless for six months, must be acquitted of the charge of originating the disease. The swab results quoted do not include visitors, whom I would impugn as being much more likely to introduce the organisms, not only to the two cases, but also to the nasal carrier. In these days diphtheria patients are retained in isolation until successive "freedom" swabs have been obtained, and chronic nasal carriers are rare.

Even with fully inoculated patients, clinical phenomena should be the guide to therapy, for there are some individuals unable to maintain immunity against the gravis strains of diphtheria bacilli. If there is relatively painless oedema of the fauces and neck glands with the presence of membrane, large doses of diphtheria antitoxin should be given at once—I am, etc.,

JAMES GRANT
Medical Officer of Health, Gateshead

The Surgeon and the Anaesthetist

SIR—I have followed with great interest the discussion on anaesthesia and anaesthetics which has followed the letter from Dr. Elam (Feb. 19, p. 263) on the advisability of publication of all deaths under anaesthesia, which at present are far too high. He says "it does not at present seem that a noticeable drift away from inhalation anaesthesia and the adoption of other methods are leading to improved results, rather the reverse. A false sense of security will arise, and 'modern anaesthesia' will become (if it has not already done so) far more dangerous than chloroform anaesthesia at its worst." A letter from Dr. Parry Price in the same issue takes the ultra modern view of many of the younger generation—that chloroform should be entirely discarded in favour of other methods, such as intravenous injection of pentothal.

Chloroform inhalation still has some advocates, especially perhaps among the older generation. There are two reasons why chloroform is less in favour, especially among professional anaesthetists, than ether, gas and oxygen, and intravenous injections of a new and relatively untried drug, such as pentothal. First, there is a widespread idea, which I believe to be entirely without justification, that light chloroform anaesthesia is especially dangerous, and that sudden death from vagus inhibition may accompany even a trivial operation unless the patient is fully under the anaesthetic. This seems to be a tradition handed on by some physiologists who have had no surgical experience, and I am quite sure it is entirely wrong. The first effect of light chloroform anaesthesia is upon lower sensory centres, producing analgesia, before there is any interference with special senses or the slightest mental confusion; in fact, the sense of hearing becomes if anything more acute. The patient can answer questions, and open his mouth while sitting up in bed and minor operations can be performed, such as tooth extraction, opening a superficial abscess, or removal of a packing in a wound, while the patient knows what is being done but feels no pain, and there is no sign of nausea or disturbance of any kind.

Another reason for the unpopularity of chloroform is that a death during the administration of chloroform is in the vast majority of cases the fault of the anaesthetist and due to an overdose of the anaesthetic narcotizing the respiratory and vasomotor centres in the medulla. It occurs on the operating table, entailing an inquest, while a death from ether, when it does take place, more often occurs later and there is no inquiry.

The surgeon should choose the anaesthetist who will give the anaesthetic he prefers in the manner required and not continue the inhalant on unduly. It too often happens that the patient is still deeply under the anaesthetic when the operation is over, and may not recover consciousness for perhaps an hour after returning to the ward. Unless he is carefully watched by an efficient nurse a catastrophe may occur, such as the sudden pulling out of a tube in the intestine draining the bowel, with fatal results. The patient should be recovering consciousness when the operation is nearly over, and be fully conscious when returned to the ward. The post-operative nausea and vomiting will be much less prolonged. Chloroform is more agreeable to the patient than ether even when both are given by an

open method, and a comfortable and quiet night before the operation may be obtained by a small injection of morphine and atropine or a drug such as omnopon.

Pentothal, which seems to be so popular at the present time, is by no means free from danger, and the dose cannot be as accurately judged and fitted to the requirement of the operation. When once injected into the blood it cannot be removed until its time is up. In your issue for July 15 (p. 93) there is a letter on pentothal anaesthesia in which the writer claims to have used pentothal extensively since it came on the market, and attributes the fact that he has never yet had a fatality to a very lively respect for this powerful anaesthetic agent. To avoid fatalities he would insist on the following: It should be administered by experienced anaesthetists only, no rank-and-file medical officer should be allowed to use this powerful—dangerous if you like—drug, he gives a list of the cases in which it should never be used if anxiety is to be avoided; the following should always be at hand: oxygen, picrotoxin, ephedrine, and coramine, and the doctor conducting the anaesthetic should know how and when to use them. "Even the most experienced anaesthetist," he writes, "exercising the greatest care and vigilance, will get when he least expects it a reminder that pentothal anaesthesia is not always 'child's play'." What an extraordinary advertisement from an ardent "fan"! However, he used it to extract four teeth! Surely a whiff of the despised chloroform would be quite sufficient, as I have proved on many occasions, and quite free from any danger—I am, etc.

Worthing

HERBERT H. BROWN.

Chloroform in India

SIR—In recent correspondence in the *B.M.J.* about the merits and particularly, the demerits of chloroform a few important points were not mentioned. This agent has long been used in many parts of the world, including outlying small free hospitals in India, where modern expensive gases and apparatus are not yet available.

While fully aware of the dangers of chloroform and the undesirability of its use certain factors make chloroform less toxic and relatively safer in a healthy Indian than in a European. This is due to the Indian diet, which is principally carbohydrate and starch, in contrast to the predominantly nitrogenous diet of the West. The population in India is mainly vegetarian. The cereals, pulses and grams, and fruits contain a high percentage of carbohydrates. For instance, the carbohydrate content of the foods in common use is: rice 79%, wheat 74%, maize 66%, bajra 67%, cholam 74%, pulses and grams all above 55%, bananas 36%, plantains 24%, dates 67%, figs 17%, grapes 10%, etc. In addition mangoes, jack-fruits, water melons, oranges, etc., abound in India; and those concerned in growing sugar-canes and making molasses eat both. Buffaloes' milk and various sweetmeats made of milk and sugar are abundantly taken. The selling of freshly extracted sugar cane juice and sweetmeats is a common sight in the streets of Indian towns and cities.

Under these dietetic conditions the livers of Indians are well replenished with glycogen, which would hardly be the case with Western people with their almost wholly nitrogenous diet. Sugar tolerance is usually higher in Indians than in Europeans. It has also been recently shown that glucose strengthens the cardiac muscle, and that if an adequate amount of vitamin B₂ is taken in the pre-operative diet respiratory enzymes are well produced in the system, and so breathing troubles, other than obstructive, are to some extent prevented. Wheat, pulses etc., which abound in Northern India, contain vitamin B₂, and these and other carbohydrates, and milk products, account for the health and great bodily strength of the people there. Chloroform does not produce any serious hepatotoxic effect in these healthy people, whose livers contain adequate glycogen; also there is hardly any respiratory trouble, owing to sufficient respiratory enzymes—viz., flavo protein, and coenzymes I and II—from the use of wheat, bajra flour, or maize, and also of toddy, which contains yeast.

From my long experience I am convinced that in strong, healthy, and active Indians living on rich carbohydrate diet the careful use of chloroform merely for inducing anaesthesia produces scarcely any hepatotoxic effect or depression of

respiration and circulation. Any temporary reaction on the liver can be safeguarded by pre-operative use of glucose and post-operative infusions of glucose with insulin.

In certain places where chloroform-ether mixtures were used no serious toxic effects were observed; relaxation was easily obtained and maintained, and no convulsions were seen even in very hot weather. The mixture seems to prevent ether spasms and convulsions, as less ether is needed. Certain medicines containing chloroform are drunk for long periods as carminatives, etc.—e.g., spiritus chloroformi (5%), emulsio chloroformi (5%), chlorodyne, cremocarbonates—with no toxic results. Hepatotoxic effects are marked in habitual alcoholics, in whom chloroform must be avoided. As no other cheap anaesthetic agent may be readily available in outlying dispensaries and small hospitals or to general practitioners, the teaching to students of the correct methods of chloroform administration cannot yet be dispensed with. It would be a blessing if some method or drug were found which completely counteracted or prevented the toxic effects of chloroform. Sodium xanthine is said to protect against liver damage. In places where gas and intravenous barbiturates, or even ethyl chloride, are not yet easily available for all cases, the trouble and unpleasantness of induction with pure ether and the large quantity of this agent needed with the open method in the great heat of summer, with consequent danger of convulsions, are all obviated by careful induction with chloroform, and its judicious use.—I am, etc.,

The So-called Meigs's Syndrome

SIR,—I read with interest the report by A. C. Clay *et al.* on two cases of fibroma of the ovary associated with hydrothorax and ascites (July 22, p. 113), but would like to protest against the name of Meigs, who only wrote of the condition in 1934, being associated with the syndrome. The description of this syndrome is by no means of recent origin, as I was told about it when I was a student 30 years ago, and have personally taught it to my students, as a rare possibility, for over 20 years. It is definitely recorded in Eden and Lockyer's *New System of Gynaecology*, published in 1917. If any name is to be associated with this syndrome, surely it should be that of the man who first described it, and, therefore, the name of either Cullingworth or Lawson Tait should be substituted.

The syndrome is certainly an uncommon occurrence, but I do not think nearly so rare as the recent literature on the subject would suggest. This is probably because, in this country at any rate, such cases are not commonly recorded in the medical journals, though most gynaecologists have encountered at least one case.—I am, etc.,

W. F. THEODORE HAULTAIN, F.R.C.S.Ed., F.R.C.O.G.

Edinburgh

Problem of the Small Bladder

SIR,—I have given particular attention to the type of case with chronic frequency that Mr. Sheppard mentions in your issue of July 22 (p. 124), and I have been able to benefit many of them after investigating the posterior urethra; for urethroscopy often shows that there is a chronic inflammatory process in the locality mentioned. This is so in spite of a sterile urine and absence of any indication on rectal examination that there is any pathological process present in this region.

In the male the common findings are small granulomata or polypi on the verumontanum or in one or other prostatic sinus, or small nodular projections (hillocks) on the lateral walls or roof of the posterior urethra. In many females with chronic frequency and in many children with enuresis—many of whom also have frequency—hillocks and polypi are also found in the posterior urethra. There seems good reason to believe that many of these lesions are the result of simple infections which occur insidiously in childhood.

The best urethroscope that I have found for these investigations in adults is the Joly examining (Charrière 24). It is important to avoid a large instrument. A good local anaesthetic should be used. In children I use a Gekering type

urethroscope (Charrière 16); a general anaesthetic is necessary for these.

In those cases in which the polypi, etc., are firm and fleshy destruction by fulguration with a weak current (1 unit on G-U machine) is necessary. In other cases gentle and intermittent dilatation of the posterior urethra regularly has a beneficial effect on the symptoms. For adult males well-softened gum-elastic bougies should be used at first after a good local anaesthetic; for adult females straight metal bougies; for children special curved metal bougies, under a general anaesthetic of course. Great care must be taken to see that the increase in size of the successive instruments used is finely graded. It is my custom with male adults not to take the dilatation above 26 Charrière (15 Eng.), except in special cases. Meatotomy is sometimes necessary before the patient can get the benefit of the larger sizes. In female adults I aim at 32 Charrière as the top size. The treatment of children is too complex to be dealt with here (see *Proc. roy. Soc. Med.*, 1944, 37, 345). The benefit from dilatation is apparently in the promotion of drainage from the chronic inflammatory foci.

It is a most interesting study to examine some of these cases with the urethroscope after several dilatations and to note the improvement which has occurred. This often applies to gland orifices in the anterior urethra. Routine urethroscopy is most simply done in women. In adults the intervals between the dilatations should be gradually increased; my routine in an individual case is to give the dilatations at the following intervals: 3, 4, 6, 8, 12, 16, and 32 weeks. Over-frequent dilatation is certainly harmful.

I have come in contact with a number of patients who were discharged from the Services because of frequency or enuresis, whom I was able to help because of the urethroscopic findings.—I am, etc.,

London, W 1.

H. P. WINSBURY-WHITE.

Site for Intramuscular Injection

SIR,—I have read with interest the letters of Prof. Grey Turner, Mr. Sydney Boyd, and Dr. Laughton Scott. Without entering into the controversy as to whether the buttock or the lateral aspect of the thigh is the better site, I think that three important points arise from their letters.

First, if the correct part of the buttock is used there should be no danger of injuring the sciatic nerve. The right site for an injection into the buttock is in the upper anterior quadrant an inch or two below the iliac crest. If this area is used the point of the needle will be at least as far from the sciatic nerve as it would be in the vastus externus. Secondly, wherever an intramuscular injection is given the needle must be long enough to pierce the overlying fat and reach the muscle. Thirdly, when it is intended that an injection should be intramuscular, before the plunger is pressed home it should be withdrawn to make sure that the injection is not going to be intravenous, no matter what the site of choice.

If these three points are granted then it would appear that these three writers are really criticizing technique rather than the site of injection, and therefore are pointing to the bad teaching of technique in this matter to students and nurses.—I am, etc.,

Hartford, Cheshire.

EVAN C. WYNNE-EDWARDS.

Symptoms of Hiatus Hernia

SIR,—With reference to the excellent leading article on hiatus hernia (July 15, p. 83) may I mention an additional symptom which is quite amusing if somewhat unusual.

A very wealthy lady complained for years of substernal pain and heartburn. This was accentuated by the emotional stress of having to attend official dinners, to which function she was compelled by the social position of her husband. She also knew that she would experience a most distressing fullness and epigastric pain immediately at the beginning of the meal. Her medical advisers came to the conclusion that her complaint was a form of hysterical escapism from a loathsome duty. This view seemed confirmed by the story of the husband that the condition could be prevented and relief obtained if the patient had several glasses of champagne while dressing for the dinner.

Eventually, however, the diagnosis of a hiatus hernia was made by careful x-ray examination. The explanation of the effect of

champagne was that the carbon dioxide formed a gas bubble and the small herniated portion of the stomach was drawn back into the abdomen. I have seen the same effect achieved by giving soda-water.

The above story was told to me by my teacher and former chief, Dr Julius Bauer, now professor of clinical medicine, Los Angeles, California—I am, etc.,

London S.W.3

V. C. MEDVEI

Chemotherapy in Otitis Media

SIR—I am inclined to agree with Mr G. H. Steele that general practitioners have had quite a lot of experience with sulphonamides in these cases—by which I mean acute otitis media—and when I say acute otitis media I do not mean “acute ears,” acute otitis externa, acute catarrhal otitis media, external haemorrhagic bullous otitis, herpes oticus, or even “fungus otitis media.” I mean acute otitis media. Moreover, the experience of some general practitioners in the use of sulphonamides has been sufficiently extensive under all conditions to enable them to speak with what Mr Steele calls—not unreasonably—real authority. In my experience an otologist who has had no more than as Mr Dingley puts it, “at least a year or otoscopic experience” has still a long way to travel before he could be considered competent to diagnose all the different varieties of acute otitis via the speculum, even with the added advantage of personal tuition and a selected series of cases. I would certainly not accept the opinion of such a gentleman without verification. It should be realized that since the introduction of the electric auroscope the general practitioner has become much more familiar with abnormalities of the drum, especially if he has the patience to carry out the toilet of the meatus. Failure to do this may lead him into errors of which he may later feel, as I have felt, heartily ashamed. The important thing is for him to be able to recognize a normal drum.

If sulphonamides properly administered bring about a subsidence of symptoms and resolution, surely it is an indication that they have been properly used and have effected their purpose. I absolutely deny that they can “mask symptoms” if they are given adequately in cases in which experience has proved them to be effective. The inept and pointless complimentary gesture which Mr Dingley makes to the general practitioner by stating that his “valuable contribution” is in his “knowledge of his patient and the constitutional aspect of his illness” is of no more value than the knowledge of his patient and the constitutional nature of his illness are likely to be in the type of cases under notice—which is precisely nil—I am, etc.

Brookwood (Surrey)

H. M. STANLEY TURNER.

SIR—I have been extremely interested in the correspondence on this subject, and especially in the excellent article by Mr A. R. Dingley (June 3, p. 747). The following case may be of interest in this connexion.

A few weeks ago I was asked to see a doctor's child aged 5, who had the following history. Five weeks previously the child had had an attack of tonsillitis followed seven days later by earache in the right and left ears. Sulphathiazole 0.25 g. four hourly was given for two and a half days, but was discontinued owing to difficulty in getting the child to take the drug. There was slight otorrhoea from the left ear for three or four days and this cleared up. The right ear also discharged at this time—i.e., seven days after the onset of tonsillitis—and this appeared to clear up, but recurred several times and then appeared to clear up. One morning five weeks after the onset of tonsillitis the child complained of pain on lying on the right side, and it was noticed that the right ear was protruding outwards. I was then asked to see the child, and found a protruding right ear, and swelling and tenderness over the right mastoid. The right external meatus was full of thick creamy pus—a typical acute suppurative mastoiditis. The left ear was normal. Cortical mastoidectomy was performed. Very extensive suppuration was found, the whole of the mastoid cells were full of thick creamy pus. The tympanic membrane was thickened and oedematous and was incised at the same time. Recovery has been complete.

While this case did not have the requisite amount of sulphonamide therapy what it had was given very early. I feel, however, that an early myringotomy may well have prevented the unfortunate sequel—i.e., suppurative mastoiditis. It is my experience that early myringotomy followed by sulphonamide

therapy gives the best results in otitis media, and I am in complete agreement with all that Mr Dingley has so admirably explained—I am, etc.,

Poole Dorset

A. MACKENZIE ROSS

Septic Tonsils in the Soldier

SIR—Major Gen. Philip Mitchiner (July 8, p. 37) writes “Tonsillectomies and operations on the nasal septum undoubtedly constitute scalpels for the operating surgeons, but how often do they make the patient any more fit for full duty in the rough and tumble of Service life?” The statement made here is a gratuitous insult to ENT surgeons. Most of us will not think very highly of a surgeon, however distinguished, who looks on his operations as “scalpels.” But the question raised is more important, and one aspect of it is of immediate interest. As an ENT surgeon I have been disagreeably surprised to find soldiers evacuated from France for tonsillitis, a preventable disease and others with various rheumatic conditions associated with septic tonsils. Are we to do nothing for them?—I am, etc.,

E. S. BLUNT HAMILTON

Episiotomy

SIR—As a mere GP I hesitate to challenge Dr Josephine Barnes's criticism (July 1, p. 23) of my memorandum of June 17 (p. 813). This article was written from the standpoint of domiciliary midwifery, and I am sure Dr Barnes will admit that conditions of work are often very different from those obtaining in hospital.

The method illustrated was developed primarily to secure accurate apposition of the wound edges, and not necessarily to avoid anaesthesia after the birth. Personally (and here I would welcome the views of other general practitioners) I have long given up using catgut in the perineum, owing to the risk of sepsis, but such stitches, if considered necessary, could, of course, be inserted after the birth.

I am aware of the dangers attending the use of chloroform in the third stage, and never employ a general anaesthetic other than nitrous oxide. Finally, I am glad to have it confirmed on such good authority that there is a wider scope for episiotomy—I am, etc.,

Borrowash, Derbyshire

G. S. NEILSON DOW

Riboflavin and Allied Deficiencies

SIR—The very mass of writing on the vitamins, of which the lecture by Dr Stannus (July 22, p. 103) is an impressive example, can be confusing to the practitioner. The difficulty is to appertain to the appropriate role to each of the vitamins essential for the release of energy from carbohydrate. There are observations which suggest that riboflavin is its own cytochrome and acts as such when the usual cytochrome (haemin) is not available, as in avascular structures. A very early sign of ariboflavinosis is vascularization of the cornea, the oxygen-carrying haemin has to be brought in to maintain the life of the cornea, and it is withdrawn as soon as riboflavin is supplied in sufficient quantity.

The main purpose of carbohydrate metabolism, however, is the production of the form of energy known as muscular work, for this haemin is the cytochrome and ascorbic acid the main vitamin essential for each of the six steps of hexose breakdown. B₂ is a specific catalyst in degradation of pyruvic acid, a by-product of this reaction, and nicotinic acid is necessary for the utilization and elimination of lactic acid. Riboflavin also aids oxidation of carbohydrate, lactic acid, amino acids, and aldehyde, but there is little evidence that it is concerned with the production of muscular work. This possibly is reflected in the relative daily requirements of riboflavin (1.5 mg.) and ascorbic acid (50 mg.—).

The particular role of riboflavin in carbohydrate metabolism is probably concerned with maintaining structure as contrasted with function, for all the manifestations of ariboflavinosis quoted by Stannus are dissolutions of structure. If we compare this with the Crandon experiment we note that muscular weakness was apparent long before there was any structural damage, and that muscular strength returned immediately ascorbic acid was added to the diet.

The conclusion therefore is that riboflavin is necessary for that part of carbohydrate metabolism concerned with structure, but that it is only indirectly concerned with the conversion of glucose into muscular work.—I am, etc.,

Caernarvon.

GRIFFITH EVANS.

Epidemiology of Infective Hepatitis

SIR,—In Prof. L. J. Witts's interesting discussion of some problems of infective hepatitis in your issue of June 3 it was stressed that no animal is known which can be experimentally infected with the disease and that the discovery of such an animal would very greatly facilitate the epidemiological study of the condition. The following observation, which was made during the last war, may therefore be of interest. At Abbeville I saw a nursing sister who was convalescent from "catarrhal jaundice," and also, seated upon her shoulder, a small pet monkey. The animal at that time was undoubtedly jaundiced, and it had been in contact with the nurse during the acute phase of her illness. Unfortunately I am unable to name the species of monkey concerned, and the conjunction of the two cases may, of course, have been a mere coincidence; on the other hand the incident may possibly afford a clue to the discovery of the animal which would be so helpful in elucidating the aetiology of a disease which is causing much temporary disablement at the present time.—I am, etc.,

Southwell, Nottinghamshire.

C. H. WARNER.

Self-medication and Patent Medicines

SIR,—The article on self-medication and patent medicines (July 15, p. 87) is certainly timely, but it would have carried more weight had the number of persons questioned been greater, and if it could have been demonstrated conclusively that the medicine addicts were more unhealthy than the abstainers, or that the educated were more abstemious in the matter of drugs than the ignorant. I was thankful to find that the inquirer was tactful enough to limit his questioning to the consumers of medicine *not* taken under medical direction, otherwise the results would have been rather embarrassing.

I wonder, out of all the millions who imbibe purgatives, lubricants, anodynes, stomach medicines, etc., how many are really harmed, except financially. Compared with the pleasure derived the harm done must be negligible. Has it ever been proved, for instance, that the achlorhydria encouraged by prolonged ingestion of paraffin and alkalis has anything to do with the incidence of gastric cancer?

I can't see how, in a democracy, one can do much by legislation to curb the advertiser's flights of fancy, and why should one want to? Life is drab enough anyway. Why should the advertisers be limited to the truth any more than politicians or doctors?

In spite of the findings of Edwards and Kinsie, and the fact that believers on the whole are happier, fatter, and psychologically sounder than sceptics, education surely should be some little help in assisting us to discriminate between the fantastic and the possible. But how to set about this education? It is no good trying to enlist the aid of the Press, for they are hardly likely to bite the hand that feeds them. Fiction had a good shot at it in Wells's *Tono Bungay*, which, by the way, should make an admirable film. What about the B.B.C.? Unlike other radio systems, it at least has the advantage (we hope) that it doesn't suffer from vested interests. I should say this is broadcasting's big chance.—I am, etc.,

Thame, Oxford.

E. GRANGER.

Varicella and Herpes Zoster

SIR,—The cases of Drs. F. M. B. Allen and J. J. Manning (July 22, p. 115) have reminded me of a case of my own which had one or two additional points of interest.

The patient was a man aged 81. In 1934, when he was 73 years of age, he developed exfoliative dermatitis, which appeared to be intractable to any form of treatment and involved the whole of his skin surface. In 1935, without any preliminary symptoms, he had an acute retention of urine; his prostate proved to be grossly enlarged. He was considered to be a particularly bad operative risk on account of his skin condition, but, apart from it, he was extremely vigorous, both mentally and physically. His temperament was such that a catheter life would have been an intolerable burden, and

accordingly the risks of operative treatment were faced. After a preliminary suprapubic drainage the prostate was removed, and, following a stormy passage of a week or so, he made a complete recovery with excellent control and a clean bladder. A few weeks after his operation the exfoliative dermatitis cleared up.

On April 9, 1942, the patient's 81st birthday, I was called in to see him and found that he had a typical band of herpes zoster of about the sixth or seventh right dorsal distribution with the usual burning sensation and pain. He was kept in bed and exactly a week later a chickenpox eruption of moderate severity appeared. The distribution of the vesicles was in no way unusual and the scalp had quite a number. On April 25 his grandson aged 8, who lived in the same house, developed chickenpox, and about ten days later his granddaughter, aged 4, followed suit. The boy had a mild attack which ran a normal course. The little girl's attack was rather more severe with a comparatively large number of vesicles on the face. My original patient recovered from his herpes zoster, and, though he suffered from recurring pain in the area for several months, he was able to resume his bowls, his club, and other activities.—I am, etc.,

Preston.

F. M. ROSE.

SIR,—With reference to the two cases reported by Dr. Allen and Dr. Manning may I add yet another within my own experience.

On Dec. 11, 1942, I saw a normally very healthy man aged 40 with a profuse herpetiform eruption involving the right side of the neck and shoulder. By Dec. 22 a typical varicella was established. The noticeable point of difference in these three cases is the sequence. According to Dr. Allen's record the herpes followed the varicella after an interval of about three weeks. In Dr. Manning's case the two conditions were strictly concurrent, while in my own the varicella followed hard upon the heels of the herpes.—I am, etc.,

Yeovil.

NORMAN FLOWER.

Adoption of Children (Regulation) Act, 1939

SIR,—This Act provides that, if arrangements are being made for a child under 9 years of age to be placed in the care and possession of a person who is not the child's parent or guardian or near relation, any third party participating in such arrangement must give seven days' notice to the Welfare Authority before the child is transferred to the adopter.

Recently a doctor attended a patient on the birth of her illegitimate child, and also attended a married woman who had been disappointed by the birth of a stillborn child. He introduced the two women with a view to the adoption of the illegitimate child by the married woman. Subsequently the practitioner's attention was drawn by the Welfare Authority to his failure to give the notice required by the regulations; happily, through the intervention of the Medical Defence Union, the matter was brought to a satisfactory conclusion.

The purpose of this letter is to bring to the notice of doctors, nurses, and midwives an obligation of which many may be unaware.—I am, etc.,

JAMES FENTON,
President, Medical Defence Union, Ltd.
London, W.C.1.

Character and Personality in the Medical Student

SIR,—Dr. R. John Gourlay (July 15, p. 96), for some obscure reason, appears to think I advocate a classless society. Let me assure him that this is far from being so and that I heartily agree with the greater part of his letter. Also I would like to join with him in praising ability, but not only as manifest in "our men of ability" but also in all its many other forms.

All that I ask is that ability is given a fair chance. If the dustman's son wishes to become a doctor, and is able, let him be given every facility to succeed. At the same time if the doctor's son wishes to become a doctor, and is unable, let him find an occupation more suited to his ability. The laws of heredity and the theory of evolution remain unchallenged and irrelevant. Let ability, not wealth, be the key to success and social distinction. Hitherto wealth has been the key and ability has merely turned it in the lock. Ability by itself has been all but impotent. It would be impertinent to ask how many doctors would be in their present eminent positions if they had not had the money to provide for their education; their ability, inherited or not, by itself would have availed them as little as does that of millions of the other members of the community. If ability is given every chance in its own right,

it is immaterial whether or not it results from inheritance or environment.

So long as ability is subordinate to wealth on the road to success and eminence just so long will our standards of eminence remain mere shadows of what they might be. And wealth will remain the source of wealth, making real progress impossible.

Finally let me assure Dr Gourlay that far from putting the clock back 2,000 years I am attempting to push it round a little faster than, regrettably, many would have it go—I am, etc.,

Park View Hospital

H E VICKERS

Ophthalmologist and Optician

SIR.—As a general practitioner who also derived in income, before medical qualification, as a retractionist I should like to add a suggestion to the contribution of your correspondent Dr Geoffrey Ebbage. I have always found that opticians have great difficulty in *not* prescribing lenses, and only the few conscientious retractionists refer their patients to the medical practitioner. I suggest that (a) the training and examinations in retraction and orthoptics should be intensified, and the recognition of organic disease minimized, and (b) that opticians should treat only those patients who have been seen and examined by their medical adviser and referred to the optician—I am, etc.,

Salford

BERNARD WILKINS M.B.

Obituary

B. J. BRANDSON M.D., F.R.C.S.(C)

Dr Brandur Jonsson Brandson, professor emeritus of surgery, died at his home in Winnipeg on June 20. Few doctors in Western Canada have been more widely known and deeply loved or have exercised a greater influence among their own people in the field of medicine.

Born in Iceland on June 1, 1874, he came with his parents to Minnesota at the age of 4. He graduated in arts from Gustavus Adolphus College at St. Peters, Minn., and in medicine from Manitoba Medical College in 1900. For five years, interrupted by a year in Great Britain, he practised at Edinburg, N.D. With his life long friend, Dr O. Bjornson, he returned to Winnipeg in 1905. For a time they practised in partnership, but later each took the line of work for which he was specially fitted. Dr Bjornson became professor, then emeritus professor, of obstetrics, while Dr Brandson rose by successive steps to be lecturer in surgery, associate professor, professor, head of the department of surgery, 1927-34, and, on his retirement, emeritus professor. At the convocation last May the University of Manitoba conferred on him the degree of Doctor of Laws *honoris causa*. This is not the first honorary degree granted him. In 1930 he was appointed a representative from Canada to attend the millennium of the Althing, the Icelandic parliament. At Reykjavik the University of Iceland conferred the honorary degree of Doctor of Medicine. Five years later the Icelandic Government made him a Grand Knight Commander of the Royal Icelandic Order of the Falcon. At the 98th Annual Meeting of the British Medical Association, held in Winnipeg in 1930, Dr Brandson was one of the vice-presidents in the Section of Surgery. The Winnipeg Medical Society granted him life membership in 1943. He was a Fellow of the American College of Surgeons, and a Charter Fellow of the College of Physicians and Surgeons of Canada. In his arts college Dr Brandson had as his friend and classmate the late Thomas H. Johnson, who also went to live in Winnipeg and became Attorney General of Manitoba. Though Brandson took a keen interest in politics and was repeatedly urged to contest an electoral district, he never allowed his name to go for nomination. At the time of his death he was honorary president of the First Lutheran Church, Winnipeg. An institution very dear to his heart was the Icelandic Old Folks' Home at Gimli, the "Home of the Happy Sunset." He is survived by his widow, two daughters, and a son. One daughter is the wife of Major John A. Hillsman, R.C.A.M.C. over seas. The son, Lieut. Thomas L. Brandson, is believed to have been serving as paymaster on H.M.C.S. *Athabaskan*, sunk recently in conflict with German destroyers in the English Channel.

In addition to his early postgraduate year in Great Britain and the Rotunda, Dublin, he also studied in London and Vienna. He was a foremost surgeon possessing that greatest of surgical qualities—sound judgment. His enduring fame, however, will be his gifts as a teacher. Wise, prudent, humane, and above all kindly, he will be long remembered.

R. M.

Dr JOHN MURDOCH died on July 7 at his home in Chesham Place, Brighton, aged 62 after a long illness. He graduated M.B. Ch.B. Glas. in 1904 and took the F.R.C.S. Ed. in 1909. Leaving his practice in Kinross in 1914 he went to France, where he served with great gallantry, gaining the Military Cross as a combatant officer in the Argyll and Sutherland Highlanders. He was wounded and invalided out of the Army in 1916. He resumed the practice of medicine by joining the Red Cross in 1917, which he served until 1939, most of which time in the office of Commandant of the Red Cross Hospital for Officers, Brighton. In this capacity he devoted the whole of his energies to the well-being of the ex-officers under his care, and will long be remembered for his integrity and devotion to duty. He leaves a widow and two sons, both of whom are serving in the Army overseas.—G. W. B.

We regret to announce the death on July 22 of Mr ERNEST WARE, emeritus surgeon to the Hospital of St. John and St. Elizabeth in St. John's Wood, and to the Hampstead Hospital for Children. Ernest Edwin Ware had his medical training at St. Thomas's Hospital, and after qualifying in 1889 was house surgeon there. He graduated M.B., B.S. Lond. in 1891, and took the M.D. in 1893. Before settling down in surgical practice in North-West London Ernest Ware was for a time medical officer at St. Mary's Hospital for Children at Plaistow, and resident medical officer at the East London Hospital for Children, Shadwell. He was a past chairman of the Hampstead Division of the British Medical Association, and the Hampstead Medical Society, in whose work he had taken an active part for many years, made him an honorary member. He was elected F.R.C.S. Eng. in 1930 and the National University of Ireland gave him the honorary degree of M.Ch. in 1938. Another distinction, but not a medical one, which he prized was admission to the Order of Knights of St. Gregory. The Hospital of St. John and St. Elizabeth, where he had given such long and faithful service as visiting surgeon, held a requiem for him in the chapel on July 26.

Dr J. W. HYSLOP, who died on July 13 in his 75th year, was the son of the Rev J. S. Hyslop and was born in Leven, Fifeshire. He studied medicine at Edinburgh University, where he graduated M.B., Ch.B. in 1893. He was in general practice in Menston, near Leeds, for some 50 years. His interest in village life was always great and varied. He was the founder and for many years president of the Menston Amateur Operatic Society, and his keenness and organizing ability did much to make this a most successful venture with far more than a local reputation. He was also a founder of the Menston Sick Nursing Society and its secretary for many years. He held the post of superintendent of the Menston Isolation Hospital for 37 years, and only retired in June of this year. His work there was perhaps his crowning achievement, for I have never known a happier hospital. Many of the children under his care were loath to leave when their time was up, and I have heard several children ask to be taken back on the slightest pretext. The results of treatment at the hospital were excellent bearing comparison with any in the country. In 1921 Dr Hyslop was appointed a Justice of the Peace, and in recognition of his scrupulously fair dealings as a magistrate at Otley court he was recently appointed chairman of the Juvenile Panel. As a general practitioner he gained the confidence of his patients by his untiring devotion and care. Menston was indeed fortunate to have Dr Hyslop as its family doctor.—R. J. G.

We regret to announce the death on July 19 at St. Asaph of Dr HENRY LLOYD, who had been a member of the B.M.A. since 1892, served on the Welsh Committee for one term, and twice represented his Division at Annual Meetings. He studied medicine at Liverpool and University College Hospital, qualifying in 1884 and taking the M.D. degree of Durham University in 1900. When at the end of 1937 he resigned his position as district medical officer, public vaccinator, and medical officer of the St. Asaph Public Assistance Institution, he was the doyen of the medical profession in the Vale of Clwyd, and his resignation was received with much regret by the Flintshire County Council.

Dr Arthur F. Perigal writes from Hatfield: "May I be permitted to add my humble appreciation of Sir WILLIAM LISTER, whom I knew well in 1898, when he was with Marcus Gunn and I a clinical assistant at Moorfields with him. Handsome, debonaire, and kind, he was ever ready to explain and help, and was indeed a conscientious and accurate worker in spite of fatigue after some 4 or 5 hours in the vitiated atmosphere of that out-patient department. Later he was most charming and considerate to private patients sent to him, whatever their status, the memory of his friendship is most happy."

Medical News

The Conjoint Committee of Epsom College will in November award an annuity of £35 per annum to a spinster daughter of a medical man. Candidates must be Protestants and fully 65 years of age. Forms of application may be had from the Secretary's Office, Epsom College, Epsom, Surrey, and must be returned by the morning of Oct. 25.

The Mental After-Care Association (Eagle House, 110, Jermyn Street, S.W.1) will broadcast in the "Week's Good Cause" on Sunday next, Aug. 6, at 8.25 p.m.

The address of the Drugs Branch, Home Office, is now 52, Prince's Gate, South Kensington, S.W.7.

Dr. Sidney Osborn, medical officer in charge of First Aid Post, Civil Defence Casualty Service, Ipswich, has been commended for brave conduct in Civil Defence.

A notice issued by the Pharmacopoeia Commission states that potassium sulphate *British Pharmacopoeia*, 1914, may be used in place of lactose in making pulvis ipecacuanhae et opii, and that sucrose may be used, also in place of lactose, as diluent in making pepsinum and pancreatinum.

British Medical Association House, including the Library, will be closed on Saturdays during the month of August.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* during the week there was very little change in the trend of infectious diseases. Notifications of diphtheria and dysentery were respectively 66 and 22 higher than last week. Pneumonia notifications fell by 102, and measles by 35. In Durham diphtheria notifications went up from 43 to 70, the cases being widely distributed throughout the county.

The chief local returns of dysentery were: Glamorganshire 19 (Cardiff C.B. 15); Sussex, Hailsham R.D. 17; Southampton 14 (Hartley Witney R.D. 12); Lancashire 12; Essex 10.

In *Scotland* 20 more cases of dysentery were reported than last week, but there were 61 fewer cases of acute primary pneumonia. The incidence of diphtheria remained at the same low level as last week. The rise in dysentery was due to Lanark County, where the cases rose from 5 to 18. Edinburgh reported 14 cases and Glasgow 10.

In *Eire* measles notifications dropped to almost half the high level of the previous fortnight. Over half the reported cases were in Co. Clare, Ennis U.D.

Tuberculosis in London

On July 27 Mr. Willink announced the figures for tuberculosis mortality in the administrative county of London for the past nine years. The rates were:

Death Rates from Tuberculosis (All Forms) per 1,000 Population, 1935-43 (excluding Non-civilians from Sept. 3, 1939)

	Rate per 1,000	
1935	0.746	
1936	0.755	Based on total deaths and total population
1937	0.771	
1938	0.704	
1939	0.760	Excluding non-civilians from Sept. 3, 1939
1940	0.974	
1941	1.248	Based on civilian deaths and civilian population
1942	1.017	
1943	0.934	

Mr. Willink said that these figures represented the deaths of both sexes and at all ages from tuberculosis per 1,000 total population up to Sept., 1939, and per 1,000 of the civilian population after that date. They did not indicate the trend of tuberculosis mortality in London, because (1) great changes had occurred since 1939 in the sex and age proportions of London's population; and (2) medical selection for the Services left behind the bulk of tuberculous persons in the civilian population. Death rates for separate sex-age groups, which alone could indicate the real trend of mortality, could not be calculated for local areas for years since 1939, because the requisite populations were not known in detail of sex and age.

Week Ending July 22

The returns of infectious diseases in England and Wales during the week included: scarlet fever 1,461, whooping-cough 2,157, diphtheria 471, measles 2,401, acute pneumonia 374, cerebrospinal fever 46, dysentery 151, paratyphoid 4, typhoid 21.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended July 15.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland. *Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for:* (a) The 126 great towns in England and Wales (including London), (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1944					1943 (Corresponding Week)

Rate per 1,000 total births (including stillborn)										
			30	—	—		27	—	—	—

* Measles and whooping-cough are not notifiable diseases in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

The following candidates have been approved at the examinations indicated:

FINAL M.B.—Part I (Surgery, Midwifery, and Gynaecology): P. Allebone, J. D. Andrew, T. C. Beard, M. F. Bethell, D. G. Bratherton, G. N. Cooke, G. S. Crockett, J. M. Davis, C. H. de Boer, H. J. Dismorr, E. J. Dowling, J. A. Dudgeon, M. A. Epsiein, G. L. Evans, T. P. S. Frew, J. S. R. Golding, B. A. J. C. Gregory, P. F. Haggart, D. W. Hall, F. G. J. Hayhoe, P. R. Headley, E. W. Heining, A. Hill, S. M. Hilton, J. G. Holmes, W. R. Horsfall, E. G. Jenner, E. D. Jones, J. D. S. Knight, W. Kwantes, K. W. Leech, J. R. May, E. T. G. Meade-Waldo, D. J. Morton, J. P. D. Mounsey, E. W. Nation, G. A. Newsholme, M. Newton, M. B. Paul, G. F. Roberts, J. M. Roberts, P. K. Robinson, F. S. Sinker, C. A. Storr, J. M. Stowers, J. M. Thomas, K. Till, B. H. Vawdrey, M. H. D. Veale, P. R. Westall, D. Wilkes, R. J. Williams, L. Wolman, M. F. T. Yealland, G. Yerbury. **Women:** E. M. Davies, M. H. Jordan.

Part II (Principles and Practice of Physic, Pathology and Pharmacology): T. S. L. Beswick, R. H. Boardman, D. G. Bratherton, D. Brazier, A. Comfort, G. S. Crockett, P. D. B. Davies, P. J. De Vescovi, J. A. Dudgeon, D. A. W. Edwards, M. A. Floyer, P. H. Friedlander, J. W. Fullerton, C. R. H. Green, J. A. Harrington, C. E. Hartley, S. M. Hilton, R. F. Hollick, N. S. Hooton, W. R. Horsfall, G. I. C. Ingram, R. E. Irvine, J. Lorber, M. B. Matthews, J. R. May, J. M. Morgan, M. Newton, K. N. V. Palmer, P. B. Philip-Smith, D. A. Pond, P. D. G. Pugh, G. F. Roberts, J. Roche, B. Schofield, J. A. Shiers, J. F. N. Sidebotham, C. A. Storr, J. M. Stowers, M. Symons, R. G. Turner, D. R. D. Vanstone, B. H. Vawdrey, D. G. Veater, P. Venables, S. M. Vine, P. R. Westall, A. P. Wingate, L. Wolman, G. S. Yeoh. **Women:** R. C. A. Hunter, R. S. Mitchison, M. M. Tunstall-Behtens.

The Raymond Horton-Smith Prize for the academic year 1942-3 is not awarded.

The annual report of the Director of the Molteno Institute of Biology and Parasitology mentions that Prof. D. Keilin and Drs. E. F. Hartree, R. Hill, T. Mann, H. Laser, and M. F. Perutz have continued their work on the properties and function of intracellular catalysts and oxygen carriers. Dr. P. Tate continued to study the morphology and biology of Dipterous larvae; Dr. Ann Bishop has continued her work on the chemotherapy of avian malaria, on behalf of the Medical Research Council; Dr. Kenneth Smith and Mr. R. Markham have continued their studies on plant viruses, including new viruses attacking medicinal plants; and Dr. W. P. Rogers joined the Institute in October, 1942, to study the physiology and chemotherapy of parasitic nematodes.

UNIVERSITY OF DURHAM

At a degree ceremony held in the Hall of the Castle at Durham on July 11 the Honorary D.C.L. of the University was conferred upon Dr. Gordon M. Holmes, F.R.S. In the course of his presentation speech the Public Orator recalled that Dr. Gordon Holmes graduated in arts and medicine at Trinity College, Dublin, and after post-graduate study abroad began his lifelong association with the National Hospital for Nervous Diseases, Queen Square. There he followed in the steps of distinguished teachers, and his wards in turn became the meeting-place of students from all parts of the world. To precision and clinical acumen he added an intimate knowledge of the work of others. His pre-eminence as a neurologist was recognized by his election as president of the Second International Congress of Neurology in 1935. He was for many years the indefatigable editor of *Brain*, and he maintained throughout life his interest in general medicine. In the last war Dr. Gordon Holmes was consulting neurologist to the B.E.F. in France; in the present war he served as chief consultant to the E.M.S. The University of Durham honoured him as a great teacher and as the leading representative to-day of the enduring English tradition of clinical neurology.

UNIVERSITY OF GLASGOW

The degree of M.D. was conferred *in absentia* on Fl. Lieut. Nathan Sher, M.B., Ch.B., on July 22.

UNIVERSITY OF ABERDEEN

At the Graduation Ceremony on June 29 Reginald Joseph Twort received the degree of M.D., with commendation for his thesis.

UNIVERSITY OF WALES

THE WELSH NATIONAL SCHOOL OF MEDICINE

The following candidates have satisfied the examiners at the examination indicated:

M.B. B.Ch.—Surgery: Stuart Brest, L. G. G. Davies, E. M. L. Evans, Julia P. Gibbs, B. E. Heard, D. C. W. Jenkins, D. O. Lewis, Sarah M. Lewis, W. T. Lloyd, B. H. McCracken, Mary W. Owen, R. M. E. Seal, J. E. T. Sobey, M. J. Tanner, J. W. Thomas, H. O. Williams, P. R. J. Williams, Winifred S. Williams.

1 With distinction.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Alitology Westcent, London*. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London*.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent, London*.

B.M.A. SCOTTISH OFFICE: 7, Drumshugh Gardens, Edinburgh.

ANY QUESTIONS?

Some Points about Blood Transfusion

Q.—(1) What is the total amount of blood in the body? (2) How much blood can a person lose in a single bleeding—e.g., from a war or air-raid wound—without loss of life? (3) How many pints of blood or other transfusion fluid can a patient be given with safety at one transfusion?

A.—The total amount of blood in the body is in the neighbourhood of 11 pints. How much blood a person can lose in a single bleeding depends on the rate of loss. It is possible to lose a larger quantity if the loss is slow than if the loss is rapid. Again, there is a very great variation in the response of individuals to the loss of blood, and it would be difficult to give a categorical answer to the question, How much blood can a single person lose without loss of life? Probably if more than half the total blood is lost rapidly the outlook is not good. Again, the answer to the question, How many pints of blood or other transfusion fluid can a patient be given at one transfusion? is difficult. Experience in the present war has shown that no rule can be laid down as to dosage of transfusion fluids, except to say that enough fluid must be given to raise the blood pressure to 100 mm. Hg and maintain it there. In one individual 1 pint may do this. In another it may require 6 pints or more. It is certainly safe to give as much as 2 pints in a quarter of an hour to a shocked individual, and this can then be followed by further amounts at a slower rate. Blood-pressure readings are essential in order to regulate dosage.

The above applies, of course, to traumatic injuries. The question of a sick person is very different. The sick individual often has a cardiovascular system which is already damaged, and in such a case the rapid administration of large quantities of fluid is contra-indicated. Two to three pints given at a rate of 40 drops a minute is the largest amount one would probably give to a sick person who was not actually bleeding at the time of transfusion.

Vaginal Pessary

Q.—In your "Any Questions?" section of July 1 (p. 33) you state that the most efficient and least harmful vaginal pessary is one of phenyl mercuric acetate. Could you give me more information? I should also be glad of advice as to the most satisfactory mechanical contraceptive pessary for a normal vagina.

A.—For further information regarding phenyl mercuric acetate the inquirer should refer to the article mentioned previously (*Lancet*, 1928, 2, 882). Taking into consideration such factors as simplicity of application, harmlessness, and reasonable safety, the most satisfactory mechanical contraceptive for the average case is the Dutch cap vaginal diaphragm or pessary. The sizes vary from 50 to 90 mm. (diameter). It should fit the vaginal vault accurately, and this means a careful choice of size in each case. Moreover, it should not be used alone but in conjunction with a contraceptive paste or jelly. These appliances are supplied by most firms specializing in contraceptives, together with full instructions as to their use. An important point in technique is that the Dutch cap should not be removed until about eight hours after coitus.

Parasympathomimetic Drugs

Q.—When drugs such as carbachol, which act on the parasympathetic nervous system, are administered, is their effect equally great on all those parts supplied with parasympathetic nerves? Is the vasodilatation that follows administration evidence of the existence of vasodilator nerves of parasympathetic origin? Could you state briefly what are the main clinical indications for administering carbachol, and what are the risks attached to its use?

A.—The intestine and the bladder appear to be particularly sensitive to carbachol (doryl); the heart and blood vessels to acetylcholine (methylcholine). These differences in sensitivity of the different parts of the body are not very great and cannot readily

demonstrated in experiments on animals. A clearer difference between these two drugs is that carbachol has nicotine actions on autonomic ganglia and that mechlorin does not have these actions.

In practically all the places in the body where choline esters act there is a nerve which liberates a choline ester locally, but there is a logical necessity for the presence of such a nerve, and in a few places—e.g., the uterus of the young guinea pig—there is no nerve by argument which deduces the presence of a cholinergic nerve from the action of the drug is thus suggestive but not conclusive. The action of the drug gives no indication of the anatomical origin of the nerve. It is true that most cholinergic nerves are in the parasympathetic system, but the sympathetic system also contains many cholinergic nerves, and the nerves to voluntary muscle are cholinergic.

Carbachol has been successfully used in the treatment of postoperative intestinal atony, retention of urine, and glaucoma. In neuromuscular, high blood pressure, and arterial spasm the results have been disappointing. Numerous effects of overdosage have been described, including headache, nausea, belching, peristaltic waves, olic, diarrhoea, flushing, asthma, a fall in blood pressure and in the pulse rate. Practically all these effects can be stopped with tropine in adequate doses. A valuable review of the actions of choline esters was written by F. R. Fraser in 1938 (*British Medical Journal*, 1, 1249, 1293, and 1349).

Liquid Paraffin

Q.—There is difference of opinion as to the use of liquid paraffin internally. Some authorities describe it as a "non irritating lubricant," while others condemn its use and suggest that it delays absorption of food and vitamins. It has even been suggested that it may cause irritation and lead to malignant changes in the gastro intestinal tract. In twenty years of practice I have yet to confirm any of these pessimistic observations but I should value an authoritative opinion on the subject.

A.—There is good evidence that liquid paraffin can interfere with the absorption of carotene, vitamin D, calcium and phosphorus, and vitamin K. This may be specially important during pregnancy, and it has been suggested that whenever mineral oil is used cod liver oil should also be given. It has also been suggested that the deleterious effect of liquid paraffin on absorption can be reduced by giving it as a single dose at night. There is some evidence that the prolonged administration of liquid paraffin may cause gastro intestinal symptoms, accompanied by loss of weight in some cases though I should not contraindicate its use as a laxative when given under medical supervision. It should not be used in salad dressings. There is no evidence that it may lead to malignant changes.

Hypoproteinaemia

Q.—If nutritional oedema is in part the result of hypoproteinaemia, here is presumably a stage where hypoproteinaemia exists before the oedema appears. Can hypoproteinaemia be exactly diagnosed by the biochemist? For this purpose is an estimation of the blood protein of clinical diagnostic value in suspected cases of under nutrition?

A.—Hypoproteinaemia or an abnormal lowering of the plasma protein level, may be caused by insufficient protein intake due to undernutrition, faulty digestion of protein, inability to synthesize protein from amino-acids due to liver dysfunction, malignant disease, bowel obstruction, and increased protein loss through urapuration, ascites, nephrosis, burns, external gastro-intestinal stulac, and haemorrhage.

Hypoproteinaemia can be diagnosed by estimating the plasma proteins (for methods see *J. Biol. Chem.*, 1936, 113, 167, 1937, 120, 481). The normal range is considered to be within 60 to 75 mg per 100 c.c. Values below 60 mg are usually considered to indicate hypoproteinaemia, although Binkley (*Ann. Surg.*, 1943, 117, 748) puts the figure at 65 mg. Many surgical patients have values between 60 and 45 mg per 100 c.c., and even 30 mg has been recorded in cancer patients and in malnutrition. There are two pitfalls in the interpretation of the figures, a normal value may be found when actually the clinical manifestations of hypoproteinaemia may be present. The first pitfall is the effect of dehydration, which may increase the level of blood protein and so mask a true protein deficiency. The other pitfall is that the total protein (albumin and globulin) may be within normal limits, but the albumin fraction may be depleted. This is because the globulin fraction is sometimes increased, especially in severe infections, so that a fall in the albumin fraction is masked, unless separate estimations of albumin and globulin are carried out. The average figures for the plasma proteins are albumin 4.5%, globulin 2.0%. It is a fall in the plasma albumin that causes the clinical manifestations of hypoproteinaemia, since it is concerned mainly with the maintenance of fluid balance in the blood and tissues. To eliminate these pitfalls a red cell count or haematocrit determination should be carried out to see if there is any dehydration, and separate estimations of albumin and globulin should be made in doubtful cases. Some idea of the protein

deficiency in the tissues can be gained if the plasma albumin and blood volume are known, because for every 1 g of plasma albumin lost, 30 g of protein are lost from the tissues. Thus if the plasma albumin is 3.0 g % (average 4.5 g) and the blood volume is 5 litres, the degree of protein depletion in the body is $(4.5 - 3.0) \times 5,000 \times 30$ or 2.25 kilos. Such a figure is easily reached

100 x 1,000

in patients suffering from cancer or starvation.

(For a full discussion of hypoproteinaemia see Elman and Lischer, *Internal Abstract Surg.* 1943, 76, 503.)

Twin Injections for Varicose Veins

Q.—In using twin injections of quinine-urethane and lithium salicylate for varicose veins does it matter in which order these solutions are used and if so why?

A.—No, the order does not matter, but the level at which they are injected is significant. Quinine and urethane is lighter than blood and therefore should be injected at the lower end of the length of vein it is desired to thrombose. Lithium salicylate is heavier than blood and is therefore injected at the upper end of the

vein requiring to be sclerosed. The two substances meet in the vein and form a sticky precipitate with a powerful sclerosing action. Quinine diffuses up the vein, the lithocaine gravitates down, they are both sclerosing in their actions individually and their power is enhanced when being used together in this way. I enclose a diagram illustrating this.

Hay-fever

Q.—In the second week of July a girl aged 10 was playing in some long overgrown grass and within half an hour of this developed urticarial patches on the back and considerable oedema of both eyelids, the eyes being almost closed as a result. The conjunctivae were slightly injected. There was no accompanying hay fever. Was this an allergic reaction to Timothy grass pollen? What was the path of entry of the offending protein, and would there be any point in trying to desensitize?

A.—Quite a number of children develop ocular symptoms as the first sign of hay fever. They roll in the grass, some of the pollen gets in their eyes and sets up a mild irritation. They then rub their eyes, and their hands are usually covered with pollen from pulling and handling the grass, this sets up an angioneurotic oedema of the eyelids from friction and local absorption. It is quite likely there was some accompanying urticaria of the nasal mucous membrane, but the usual objective symptoms of sneezing and running were not present. This is a pollen sensitivity probably to several of the English grasses (not necessarily Timothy), and the child should be tested with the various English grasses and a course of desensitizing injections given weekly from the first week in January until the first week in June next year.

Skin Testing by Dust Extract

Q.—A book on allergy recommends skin testing by the dust of the asthmatic patient's own house. Please tell me if (and how) this is sterilized or treated before applying to the scratch, and how it is collected.

A.—Dust extract is prepared, if possible, from the contents of the vacuum cleaner applied particularly to mattresses and upholstered furniture rather than to carpets and rugs, as ordinary street dust is relatively inert. The dust is first defatted with ether, and each 25 g. of the dried defatted dust is covered with 100 ml. of Coca's solution (an antiseptic specially buffered saline solution, pH 7.0) and allowed to stand for 24 hours. The solution is filtered first through paper to clear it; and then through a Seitz filter to render it bacterium-free, as heat sterilization would tend to destroy its allergic properties. For a scratch test the resulting fluid may be used, but for intradermal testing it should be diluted 1:100. Coca's solution is used as a control.

Motility of Spermatozoa

Q.—A man aged 38, married 10 years, is anxious to have children. His wife is aged 36. Both have recently been examined by a competent gynaecologist and urologist respectively. The spermatozoa of the husband were found to be non-motile, and therefore presumably dead. The patient was advised to have injections of chorionic gonadotrophin and of follicle-stimulating hormone. (1) What effect, if any, are these substances likely to have on the non-motile spermatozoa? (2) If the effect of the hormones is to cause increased motility, will this persist as a permanent feature, or will retrogression take place after stopping the injections? (3) Should he have his wife with him while undergoing the treatment? (4) Can I give him any guarantee that the treatment will be successful?

A.—The absence of motility in a specimen which has not been obtained in the consulting-room without contact with rubber, and which has not been examined immediately, is of questionable significance. On several occasions I have found motile spermatozoa on direct examination in patients who believed their spermatozoa to be non-motile as the result of a laboratory report on a transported specimen, even when transferred from a condom to a glass tube. Non-motility by itself is rarely present in the absence of other abnormal features. For the purpose of answering this question, I will assume that the number of spermatozoa was considerably reduced, and that there were many pathologically shaped, as well as a high percentage of non-motile, spermatozoa. Theoretically (1) chorionic gonadotrophins should stimulate interstitial cells, whereas (2) follicle-stimulating hormone, obtained from pregnant mares' serum, should stimulate seminiferous tubules. In actual practice the first appears to work in this respect in cases of hypogonadism secondary to pituitary hypofunction, and successful results are manifested by the return of libido and erections. As regards the second, there is little or no evidence that these gonadotrophins affect the seminiferous tubules in man, or appreciably influence the character of the spermatic fluid and its contents. Certainly any effects obtained by gonadotrophic stimuli tend to retrogression after stopping the therapy. (3) As to the presence of the wife, obviously this is a necessary link in any therapy designed to produce pregnancy, but coitus is not essential for a gonadotrophic stimulus to be effective. (4) From what has been written above, it is obvious that no guarantee can be given as to the success of the treatment.

Brittle Nails after Gastrectomy

Q.—What are the cause and treatment of brittle finger-nails with many longitudinal cracks? The patient, a woman of 58, had a partial gastrectomy 10 years ago, and another gastrectomy for recurrent anastomotic ulcer 3 years ago; so that only a small portion of her stomach remains. It is only since this later operation that she has complained of the brittle cracking nails. Her nails are otherwise normal in shape (not spoon-shaped or hollow). She has no indigestion and lives on a normal mixed diet; her health is good. Her blood count is: R.B.C. 5,000,000 per c.mm.; Hb 86%; C.I. 86; W.B.C. 7,600 per c.mm. Differential: polymorphs 63%, lymphocytes 32%, large monocytes 3%, basophils nil, eosinophils 2%. R.B.C. slightly hypochromic; no abnormalities of shape or size; no nucleated R.B.C.

A.—Brittle finger-nails are not uncommon in women past middle age, particularly in time of war when additional housework increases the wear and tear on the nails. Moreover, the fat-soluble vitamins are believed to promote the health of the nails, and these principles may be reduced in the wartime diet. It is therefore not certain that the gastrectomy is the sole cause of the brittle nails, though it may well have played the chief part by impairing the absorption of the food. Iron deficiency is unlikely to be a factor, in view of the absence of anaemia and koilonychia, but calcium and fats may be lacking. These faults should be repaired by the two pints of milk a day to which this patient is entitled by her gastrectomy; this puts her into Class I (f) in the schedule of conditions qualifying for priority claims on liquid milk. Another reason why milk should

be beneficial is that the milk protein supplies organic sulphur, which is an important constituent of the nails. Nail-polish, polish-remover, and anti-cuticle solutions should be rigorously barred and a simple cream applied to the nails. Hypothyroidism must not be overlooked.

LETTERS, NOTES, ETC.**Stubborn Asthma**

Dr. A. H. DOUTHWAITE (London) writes: It may be helpful to your correspondent who raised this subject under "Any Questions?" (July 22, p. 135), to receive a suggestion that he try pethidine, 100-mg. subcutaneously, if the measures which have been advocated fail. It has none of the alarming effects of morphine, which is most dangerous in asthma. Status asthmaticus I have found to be promptly terminated by it when continuous adrenaline treatment has failed.

Artificial Insemination

A correspondent writes: Your reply concerning facilities for artificial insemination in this country (July 8, p. 65) is not strictly accurate. This method of treating sterility has for some time been employed in suitable cases at the Exeter clinic of the Family Planning Association.

Unusual Ear Conditions

Dr. S. L. ISAACS (Merthyr Tydfil) writes: I was interested in the letter of Mr. C. Hamblen-Thomas concerning large perforations due to glycerin of carbolic drops. I have found on numerous occasions that patients are in the habit of warming these drops by placing the bottle with the cork removed in about half a cupful of hot water, with the result that after standing in this position the vapour over and above the exposed glycerin acid carbolic is quickly absorbed by the glycerin (glycerin, of course, being very hygroscopic), with the obvious result that a caustic effect is produced by the addition of the water to the glycerin acid carbolic.

Clinical View of Shock

Dr. W. W. WALTHER (Queen Mary's Hospital for the East End) writes: Dr. Horace Hill (July 22, p. 126) should think again. The symptoms of shock are not identical with those occurring after the injection of histamine. As Mr. Zachary Cope points out, "the skin is usually cold and pale or cyanotic," and there is no flushing as shown by histamine.

High Birth Weights

Fl. Lieut. K. M. FOX, R.A.F., writes from India: Further to the question on high birth weights in your issue of April 8 (p. 510), which has just arrived in this country, it might interest your correspondent to know that in the summer of 1938 I was called in to attend a patient by a midwife who had made a provisional diagnosis of locked twins. However, bimanual examination soon showed that there were triplets, not twins, with the leading member of the trio presenting a large head at the os. Under anaesthesia the patient was delivered of triplets, the first two each weighing 6½ lb., and the third one a mere 5½ lb., total weight 18½ lb. Each child suckled the breast and made uneventful progress.

Trichomonas and Vaginal Discharge

Dr. W. N. MASCALL (acting director, L.C.C. (Whitechapel) Clinic) writes: I read in the *Journal* of July 22 under the heading "Vaginal Discharge after Hysterectomy" on page 135 the following sentence: "If both ovaries were removed it is possible that a trichomonas infection has been lighted up." I would like to point out that trichomonas infestation of the vagina is extremely rare either before puberty or after the menopause, whether this is natural or artificial. The average pH of the vagina is 7 at these times owing to the low glycogen content of the vaginal epithelium. The presence of glycogen is essential for the survival of the trichomonads, and it is believed the ovarian activity is essential for maintaining the necessary level in the vaginal epithelium. In adults the production of lactic acid from the glycogen by the action of Döderlein's bacillus maintains the vaginal acidity at pH 5 to 6. At this degree of acidity the *Trichomonas vaginalis* flourishes.

Offers of Hospitality for Doctors' Children

The following further offers to accommodate the children of doctors practising in dangerous areas have been received. **Dr. F.**, who practises in a rural area in Dorset, would take one child, and suggests that a girl between the ages of 3 and 5 would be best as he himself has a daughter of 4. There are no educational facilities in the district apart from the local elementary school. **Dr. G.** offers hospitality in the Isle of Man to a mother and child or to two children. If the former, help in the house would be expected, but there would be no financial expense except the cost of the journey. Any readers interested in these offers may communicate with the Secretary at B.M.A. House, Tavistock Square, W.C.1.

BRITISH MEDICAL JOURNAL

LONDON SATURDAY AUGUST 12 1944

THE NUTRITIONAL STATUS OF CAMBRIDGE SCHOOL-CHILDREN

By

JOHN YUDKIN, M.D., Ph.D., F.R.I.C.

Lieut. R.A.M.C. formerly Sir Hellyer Stewart Fellow at Dunn Nutritional Laboratory, University of Cambridge and Medical Research Council

A survey of over 1100 Cambridge children was conducted in Jan and Feb, 1942, and the majority were re-examined a year later. The purpose of the investigation was fourfold: first, to determine nutritional trends during the war by repeated examinations of the children; secondly, to see whether vitamin supplements would affect the children in any detectable way; thirdly, to examine the possible interrelation of the various physical and mental attributes of the children; and, fourthly, within the limited scope possible in an investigation which was primarily nutritional, to determine the relation between social conditions and the physical state of the children.

The children were between 4 and 11 years of age, attending elementary schools. There were altogether about 7,500 children attending these schools in Cambridge, of whom some 6,000 were between 4 and 11 years old; the children included in this investigation were thus about 15% of the total or nearly 20% of the age group 4-11. Of those between 4 and 10 years, approximately half were from a school in a fairly poor district (junior school A) and the others from a school in a comparatively well-to-do district (junior school B); the 11-year-old children were from a senior elementary school in the same better-class district as junior school B.

Although the senior school and the junior school B were so close to each other, the children attending them were not exactly comparable. The senior school received children from a rather wider area than the junior school, some of its pupils had attended the latter, but many had attended schools from slightly poorer though neighbouring districts. Moreover, the children at the senior school were a selected group in the sense that they were children from the junior schools who had not gone on to a central, secondary, or public school. This selection of children for higher education depended partly on the results of a scholarship examination held when the children were aged 10 or 11, and partly on the financial circumstances of the family. Some children, usually of poor families, did not avail themselves of the scholarships although they had reached the requisite standard at the examination; on the other hand, several of the children were sent to one of the higher schools by parents who could afford to do so, even though their children had not been awarded a scholarship.

Although, therefore, we may legitimately compare the children from the two junior schools, those from the senior school fall into a rather special category, and the findings which are recorded here must be viewed in the light of the selection to which they have been subjected.

The Investigations Undertaken

The procedure consisted of measurement of the height and weight, clinical examination, especially for signs of nutritional deficiency, examination of the gums and teeth, determination of haemoglobin, measurement of physical strength by the grip dynamometer. Additional data were obtained with the older children. Measurements of visual acuity, examination of the fundus oculi, slit lamp examination of the eyes, and measurement of intelligence and educational attainment were carried out in children of 8 years and over, and dark adaptation was determined in children of 11 years. The dark adaptation

findings are described elsewhere (Robertson and Yudkin, 1944). The results of the clinical and dental examinations, which were undertaken by the School Medical Officer and the School Dental Officer, and the results of the mental tests will be published later.

Since the first examination half of the children at each school have daily been receiving pellets containing 5,000 i.u. vitamin A, 1 mg. vitamin B₁, 25 mg. vitamin C, and 500 i.u. vitamin D so that, allowing for holidays and possible absences from school, the pellets supplied roughly half the daily requirements of these substances. The other half of the children have been given control pellets of similar size and taste but different in colour*. Neither the teachers nor the parents were aware that half of the pellets were devoid of vitamins. Records of absences from school of illness, and of general behaviour are being kept by the teachers.

At the second examination some further studies were made on about 200 of the oldest children. These tests were carried out in order to see if it could be confirmed that vitamin supplements, as has been reported, result in improved physiological performance; they have been recorded elsewhere (Jenkins and Yudkin, 1943).

Unless otherwise stated, all the results described in this paper refer to the first examination, carried out early in 1942.

FIG 1—Height of Cambridge school-children: comparison of 'good' and 'poor' school

(a) *Height and Weight*—The children were weighed completely stripped except for shorts or knickers. Their average heights and weights were higher than those reported for most other areas of the country; they are similar, for example, to the figures for 1938 for London school children, which are said to be above average for the country generally† (Benjamin, 1943).

* The pellets were generously manufactured to my specifications and given by Messrs. British Drug Houses Ltd.

† The average weights of the Cambridge children were actually very slightly lower than those recorded for the London children, if, however, one allows for the fact that the London children were weighed in their ordinary indoor clothing, the weights are slightly higher.

Nevertheless the children from the poorer junior school A were about $\frac{3}{4}$ in. shorter and $2\frac{1}{2}$ lb. lighter than those from junior school B (Figs. 1 and 2). The average heights and weights for the children of the senior school (age 11+) were as follows. Height: boys (90) 53.8 in.; girls (98) 56.0 in. Weight: boys (83) 73.8 lb.; girls (98) 76.3 lb.

FIG. 2.—Weight of Cambridge school-children: comparison of "good" and "poor" school.

FIG. 3.—The Tuxford indices of the school-children.

Many workers have attempted to express the nutritional status of a child by an index which is usually derived from combination of two or more anthropometric measurements. The most frequently used of these are derived from formulae involving the height and weight of the child. By testing a number of such formulae Huws Jones (1938) decided that the

most reliable is the Tuxford index. In its original form (Tuxford, 1917) the index is:

$$\text{Boys: } \frac{W}{H} \times \frac{(381 - \text{age in months})}{54}$$

$$\text{Girls: } \frac{W}{H} \times \frac{(354 - \text{age in months})}{48}$$

More recently, Tuxford (1942) has revised the formula so that it now becomes:

$$\text{Boys: } \frac{W}{H} \times \frac{(335 - \text{age in months})}{48}$$

$$\text{Girls: } \frac{W}{H} \times \frac{(308 - \text{age in months})}{42}$$

This latest formula is based on the figures for London school children, of 1938, which, as mentioned above, are very similar to those of our Cambridge children.

In general, such weight-for-height formulae indicate whether a child is heavy enough for his height—i.e., is well enough "covered." Now, it is well known that slight but long-continued malnutrition affects growth in height as well as in weight, and it might be thought that the retardation of both might possibly be such as to lead to no change in a weight-for-height index. This hypothesis is supported by the findings with the Cambridge school-children. Although, compared with the children from the better-class school, those from the poorer school are of inferior nutritional status, as shown by their heights, weights, and other attributes (see below), the Tuxford indices of the children of both these schools are exactly similar (Fig. 3; this includes the distribution of the indices for the senior school).

(b) *Haemoglobin*.—The haemoglobin was estimated on blood obtained from pricking the left thumb. The estimations in 1942 were carried out by using a Dare haemoglobinometer, which, through the kindness of Dr. Lucy Wills, I was able to calibrate against a standard Haldane apparatus. In 1943 the more satisfactory alkaline haematin method of King was used. Very little change in haemoglobin levels was found during the year (see below). The results shown in Fig. 4 are

FIG. 4.—The haemoglobin readings.

those obtained in 1943, using the better technique. The average haemoglobin value of the school-children was 91% (Haldane). This is much higher than that found by Wills *et al.* (1942) for London school-children and by Davidson and co-workers (1942, 1943) for Edinburgh school-children. Both groups of investigators reported an average haemoglobin level of 80-82% in children examined in 1942. As with heights and weights, children from the poorer junior school A showed lower readings (by about 2%) than those from junior school B (Fig. 4). For children of the senior school the average haemoglobin level was 92.2%. There was no difference in haemoglobin between the boys and the girls.

(c) *Dynamometer*.—The strength of grip of the right hand was measured with a hand dynamometer. The boys, as would

be expected, had a stronger grip than the girls. Once again the children from the better-class school were superior to those from the poorer school, and this was seen both in the boys and in the girls (Table I; Fig. 5).

TABLE I.—Dynamometer Readings of Cambridge School-children

Age	Average Grip in Kilogrammes					
	Junior School A		Junior School B		Senior School	
	No.	Dyn. kilo.	No.	Dyn. kilo.	No.	Dyn. kilo.
Boys						
4+	6	8.7	18	10.0		
5+	32	11.1	23	11.7		
6+	32	13.0	23	13.9		
7+	43	15.5	38	17.8		
8+	34	18.6	52	19.5		
9+	38	19.7	49	21.2		
10+	14	19.8	54	24.9		
11+					88	24.6
Girls

FIG. 5.—Dynamometer recordings of the strength of grip.

(d) *Slit-lamp Examination of the Eyes.*—The results of the examination of the eyes with the slit-lamp microscope have been described in a previous publication (Kodicek and Yudkin, 1942).

Changes between 1942 and 1943

In order to see whether the fourth year of the war had any appreciable effect on the condition of the Cambridge children, their physical measurements at the second examination were compared with those of the same age groups examined a year previously; for example, the average weight for 7-year-old children examined in 1943 has been compared with that of 7-year-old children seen in 1942. No significant difference was found in the dynamometer readings (Table II), but the average heights and weights of children in 1943 were greater than those of children of the same age a year ago (Tables III and IV). The average height of boys and girls of junior

10	68.4	67.0	68.0	71.4

school A in 1943 was about 0.6 in. more than in 1942; in the better-class junior school B it was about 0.3 in. The difference in weight was about 1½ lb. in junior school A; in junior school B there was no appreciable change in weight in the boys, but an increase of just over 1 lb. in the girls. The haemoglobin levels were about 1% higher; since, however, the estimations in 1942 and 1943 were carried out with different techniques it would be unwise to attach any great significance to the comparison of the values at the two examinations.

It is evident that, far from any adverse effect being apparent during the fourth year of the war, there was in fact an improvement in physique. There has been in general a gradual increase of height and weight of children since the beginning of the century, and that this increase is still observed suggests that the present nutrition of at least this group of children is being satisfactorily maintained. The fact that the increases in height and weight were greater in the poorer-class school is also a matter for satisfaction, indicating as it does that the differences between the nutritional status of the children of the two schools are being minimized.

Effect of Multiple Vitamin Preparations on School-children

Apart from the slit-lamp examination, all the examinations of the Cambridge school-children have been repeated after one year's feeding with the vitamin preparation. In addition, the records of the school-teachers were analysed, the opinions of the parents regarding the progress of their children were obtained, and additional examinations were made with a view to determining physiological function and the response to the vitamin C saturation test.

Physique.—No difference was detected in the gain in weight or height, in haemoglobin, or in strength of grip between the children receiving the vitamin pellets and those receiving control pellets.

Dark-adaptation.—There was no alteration in the dark-adaptation (final rod threshold) after the ingestion of the vitamin supplements (see also Robertson and Yudkin, 1944).

Illness.—The records of absences kept by the teachers have been analysed so as to give so far as is possible an idea of the relative

incidence of the major groups of illness. Since, however, the only difference was seen in those illnesses classed as respiratory (colds, coughs, bronchitis, influenza) I have for simplicity given in Table V the incidence and duration of respiratory illness only on the one hand and of all other illnesses on the other. I have also included absences due to causes other than illness. It will be seen that the "vitamin" children in both the junior schools were less often away because of colds, and on the average for a fewer number of days per illness, than the control children. This difference was not seen

The higher proportion of "vitamin" children in the senior school whose behaviour, according to the teachers, had improved is not statistically significant. On the other hand, the difference in both junior schools is significant.

In both the teachers' and the parents' records the high proportion of children who had apparently been improved by the control pellets is noteworthy, and once again stresses the importance of adequate controls in attempting to assess the value of vitamins in affecting behaviour and general health. It is perhaps worth repeating that

TABLE V.—Absences from School of Cambridge School-children

* Significant difference. † Nearly significant difference.

in the older children of the senior school. In junior school B the difference in both incidence and duration of colds was statistically significant. The difference in the number of children at this school who had no colds—76 of the 217 "vitamin" children and 55 of the 212 "control" children—was also statistically significant. In junior school A the differences were not statistically significant, but this may be due to the fact that the records of the teachers in this poorer school were not so well kept as in junior school B. For example, the average attendance during the year, according to the official records of the local education authorities, was slightly better at junior school B (90% attendance) than at junior school A (89%); yet the absences recorded by the teachers were appreciably fewer at the latter.

Behaviour.—Both the parents and the teachers were asked for their opinion regarding the children's general well-being and behaviour, the former six months after the beginning of the experiment and the teachers throughout the year. The parents were asked to state whether appetite, sleep, nervousness, and tiredness had improved, deteriorated, or remained unaltered. If we consider only those children in whom improvement was recorded for at least two of the four items mentioned, then there was in each school a slightly

neither the teachers nor the parents were aware that the pellets given to half of the children were devoid of vitamins.

Physiological Function.—Following a report by Harper *et al.* (1943) that a short period of feeding with vitamin supplements improved the physiological function of a group of cadets, some of the older children were tested to see whether a similar effect could be observed. The four tests—vital capacity, breath-holding, endurance (R.A.F. 40 mm. mercury test), and the resting heart rate—which the Manchester workers claim were affected were carried out on 178 children in March, 1943; that is, after one year of feeding with vitamin supplements. No difference was observed between the "vitamin" children and the controls (see Jenkins and Yudkin, 1943).

Vitamin C Saturation.—Senior-school boys were tested by the method of Harris and Abbasy (1937). In this method, which is modified from Harris and Ray (1933), daily doses of vitamin C equivalent to 70 mg. per stone body-weight are given at about 10.30 a.m. and the urine is for analysis collected between 2 and 4.30 p.m. The dosing and the urine collection are repeated each day for five days. An excretion of 50 mg. or more in the specimen of urine is taken to indicate saturation.

Altogether, 109 senior-school boys were investigated, of whom 22 were 11 and the remainder 12 years old. Since some of the boys were absent during the week of the test, complete records were obtained on only 95 subjects. Of these, 45 had been taking the vitamin pellets and 50 the control pellets. The average number of days to reach saturation was 1.84 in the vitamin group and 2.59 in the control group. The proportion of boys reaching saturation on each of the five days is shown in Fig. 6.

Dietary vitamin C tends to be lowest in spring and early summer, when green vegetables are difficult to obtain (Harris and Olliver, 1943). The fact that the control group was saturated in as short a time as 2½ days (average) indicates that the intake of vitamin C of these children was higher than that of other groups of children studied in the spring during the war (see, for example, Harris, 1942). This is no doubt associated with the fact that green vegetables were unusually plentiful during the winter 1942-3.

Discussion

Differences in height and weight have often been reported in children from different classes; thus, children from public schools are heavier and taller at a given age than children from elementary schools. But that differences in height and weight, and incidentally also in dynamometer readings, should exist between children of different elementary schools in the same town seems worthy of note, especially in a town like Cambridge. Cambridge is comparatively prosperous, and one would certainly not regard it as a town in which to observe widespread poverty or malnutrition. Severe or even moderate rickets, for example, is rare in Cambridge. And, as we have said, the average height and weight of the children as a whole compare favourably with those of most towns in Britain. That

TABLE VI.—Parents' Impressions of Improvement

School	Vitamin Group			Control Group		
	No. Improved	No. Not Improved	% Improved	No. Improved	No. Not Improved	% Improved
junior school A	82	107	44.2	71	102	41.0
junior school B	107	152	41.2	86	167	34.0
senior school	42	49	46.1	41	53	43.6

greater proportion of improvement in children receiving the vitamins (Table VI). The difference between the vitamin group and the control group is greatest in the children from junior school B. However, even this difference is not significant statistically.

The teachers were asked to record each month their impression of any changes in behaviour such as sociability, concentration, and memory. These records were, however, not kept very consistently, and it was difficult to assess them in any detail. All that has been done, therefore, is to note whether there has been any record of definite and maintained improvement in behaviour during the year (Table VII).

TABLE VII.—Teachers' Impressions of Improvement

School	Vitamin Group			Control Group		
	No. Improved	No. Not Improved	% Improved	No. Improved	No. Not Improved	% Improved
junior school A	63	118	35.6	44	128	25.6
junior school B	74	129	36.3	54	152	26.2
senior school	32	56	36.4	39	49	44.4

the differences are due to economic factors is supported by a study of the relation between nutritional status and family size (Yudkin, 1944a) and by the results of an investigation of children from industrial areas (Yudkin 1944b).

Limiting Factors in Nutritional Deficiency.—The absence of effect of vitamin or other nutritional therapy is not necessarily an indication that the diet was completely adequate in these essentials (Yudkin 1943, 1944c). Let us consider the results of

FIG 6—Vitamin C saturation tests

the Cambridge vitamin investigation from this point of view. Apart from the improvement in vitamin C saturation, which is simply an index of past vitamin C intake, the supplements effected an improvement only in respiratory illness and in general behaviour as assessed by the teachers. The fact that no improvement was produced in height, weight, haemoglobin, etc., even in children from the poorer school, does not mean that these are unaffected by vitamin A, B₁, C, or D. It might mean, of course, that the diets of the children supplied adequate quantities of these components. On the other hand, it might mean that the diets were deficient in other essentials in addition to these vitamins and that one or more of these other essentials was the limiting factor in growth, haemoglobin formation, and so on. An animal showing suboptimal growth on a diet slightly deficient, for example, in protein, calcium, and vitamin A will not be made to grow normally by the administration of only one of them. On the other hand, a similar degree of suboptimal growth caused by deficiency of, say, vitamin A only will be restored to normal by an increase in this factor alone.

Summary

The nutritional status of about 1,100 Cambridge school-children, determined in Jan. and Feb., 1942, was found to compare favourably with that reported for children in other parts of the country. Nevertheless, in the Cambridge children appreciable differences were seen between those living in a poorer area of the town and those in a better-class area. Compared with the latter, the children from the poorer area were on the average 0.8 in. shorter, 2.6 lb. lighter, had

2% less haemoglobin, and a grip about 1.25 kg. weaker, and showed more changes in conjunctival epithelium.

Most of the children were re-examined in Jan. and Feb., 1943. The average heights and weights were slightly greater than for children of the same age examined a year previously; in other respects no change was seen. It may be said, therefore, that no deterioration in the diets of these children had occurred between the third and fourth years of the war.

Since Feb., 1942, half of the children have been receiving vitamin pellets at school, allowing for absences and school holidays, they were thus being given a supplement containing approximately half the daily requirements of vitamins A, B₁, C, and D. The other half of the children received control pellets containing no vitamins. After a year no effect was seen in the gain in height and weight, haemoglobin, strength of grip, dark-adaptation, resting pulse rate, vital capacity, breath holding time, or endurance measured by the R.A.F. mercury test. There was, however, an improvement in vitamin C saturation, a decrease in the incidence and duration of colds, and an improvement in school behaviour as assessed by the teachers.

It is pointed out that the absence of effect on growth, haemoglobin, etc., cannot be taken to imply that these are not limited by nutritional factors.

This investigation would have been quite impossible without the co-operation of the teachers of the Cambridge schools, which was given so generously and for which I am very grateful. My thanks are due also to Dr J. A. Smyth, medical officer of health for Cambridge, Dr Janet Laidlaw, Mrs Elsie Walton, my wife, and the many friends who have helped so willingly in the collection and analysis of the results.

NUTRITION AND SCHOLASTIC ATTAINMENT

BY

I. F. MacKENZIE, M.B., D.P.H., D.T.M.&H.

Deputy County Medical Officer, Herefordshire

A measure of far reaching significance which was placed on the Statute Book in 1906 was the Education (Provision of Meals) Act. This Act granted powers enabling Education Authorities to provide meals for children in attendance at public elementary schools who were "unable by reason of lack of food to take full advantage of the education provided for them".

The inquiries of Rowntree (1900) in the city of York and the Report of the Interdepartmental Committee on Physical Deterioration (1904) had revealed that many children received quite insufficient quantities of food and that a condition of semi-starvation was rife. School-children were particularly affected and it was recognized that the lack of food produced a condition of mind and body which made educational progress extremely improbable. Thus the ultimate object of the Act was the promotion of education among the poorer sections of the community, and it is probably correct to say, from a study of the antecedents, that the means to attain this end which those who framed the Bill had in mind was the prevention of actual hunger rather than the correction of defective nutrition.

Nowadays conditions have so changed that persons living at a correspondingly low economic level are no longer encountered. On the other hand, an enormous amount of defective nutrition, due principally to a long-continuing deficient intake of essential nutrients, exists among children of school and pre-school age. Reliable evidence of this has accrued during the last few years.

through numerous investigations which need not be cited in this paper.

The question which arises at this juncture is, To what extent, if at all, does malnutrition interfere with the educational progress of a child? In other words, do the various factors which culminate in malnutrition have an adverse effect on the functioning of the brain? This point is of particular interest at the present time when plans are being formulated for reform of the educational system with a view to raising the educational level of the community. If it can be established that malnutrition reacts unfavourably on scholastic progress it is pertinent to ask if the full benefit of educational reform can be achieved without a concurrent and properly organized attempt to reduce further, or eliminate altogether, defective nutrition in school children.

Findings in Other Investigations

References in the literature to the effects of malnutrition on educational status are not numerous, but almost without exception they stress the importance of this condition as a cause of scholastic retardation. For example, Baldwin (1922) deduced from his investigations into the physical and mental growth of children that, on the average, the well-grown, well-nourished child is generally superior in its school record to the smaller child of the same age. In another investigation, in which 423 children were examined by group intelligence tests and graded physically, it was shown that 52% of the group with the highest intelligence scores had no physical defects (Sandwick, 1920). When a considerably larger group of 4,558 children was surveyed a clear correlation was established between "intelligence" and the state of the health (Pearson, 1923). A more recent statistical study of the physique of elementary-school children with special reference to their mental ability was recorded by Habakkuk (1926). He examined the records of 3,914 boys and girls aged 7 to 12 years in South Wales, and came to the conclusion that the most backward were the shortest and the most advanced the tallest. A similar attempt to correlate physical development and intelligence was undertaken in Glasgow (Dawson, 1931). The evidence obtained was such that it could be maintained that the taller children were more active mentally. In this connexion it should be stressed that there is general agreement that height is a much better index of the nutritional state than is weight. The investigations of the authors of *Genetic Studies of Genius* (Terman *et al.*, 1926) make it clear that genius and exceptional brilliance are associated with, and are probably dependent upon, a sound physique; and, to a certain extent also, upon the superabundant energy which good health promotes.

Emerson (1922) believes that though malnutrition does not cause mental deficiency it may give rise to mental retardation; while Orr (1941), in the same connexion, said that "the power to use intelligence depends upon the state of the health."

A different approach to the problem was taken by Leighton and Clark (1929). Their Scottish experiment, which involved 1,425 children of from 5 to 13 years of age, demonstrated that those who had been given a regular extra ration of milk were noticeably more alert and boisterous than the control group, which had not had extra milk. The authors stated that teachers remarked on the altered demeanour and behaviour of the boys. A somewhat similar response to an extra ration of milk was described by Corry Mann (1926). The test boys were obviously more fit and were much more high-spirited.

Present Investigations

The line of approach to the problem adopted in the present inquiry is based on the view that consistent and sympathetic observation in his class in school enables a teacher to detect quite slight deviations from the normal ability to understand and memorize, as well as permitting him to pick out those children who, without being necessarily less intelligent, are, nevertheless, not so receptive and alert mentally. It will be generally admitted that a teacher who has had considerable experience in the handling of children is usually in a position to make valuable comment on a child who has been observed in class for months or more.

An opportunity presented by a nutrition survey in a group of public elementary schools was utilized to ascertain if any evidence along this line could be secured and if my assessment

of the nutritional state bore any relation to the estimate of the teacher on the response of the child in class. Each teacher chose the pupils who, in his opinion, were the brightest and those who were slow in comparison with the class average. Classes for children under the age of 8 years were excluded from the inquiry, so the selected individuals were of varying age above 8 to school-leaving age. Children who were backward because of inherent mental defect or because of physical disability had been ascertained and provided for earlier, and the children under inquiry were therefore regarded as being of normal intelligence. The broad social and environmental conditions were identical in the case of all children. The nutrition assessment was made on the findings of a clinical examination which followed that recommended by the League of Nations Health Organization (1938), and the classification used is that sponsored by the Board of Education (1934).

Results of the Investigation

(a) *Total Figures.*—In Table I the numbers of bright and slow children in each of the four nutrition grades, and the respective percentages, are set out.

TABLE I

Category	Nutrition A (Excellent)		Nutrition B (Normal)		Nutrition C (Slightly Subnormal)		Nutrition D (Bad)	
	No.	%	No.	%	No.	%	No.	%
Bright (355)	100	28.2	235	66.2	20	5.6	0	—
Slow (357)	24	6.7	251	70.3	79	22.1	3	0.9

A total of 712 children (355 bright and 357 slow) were subject to inquiry. Out of 355 bright children 100 (28.2%) were Nutrition A and 20 (5.6%) were Nutrition C. The remaining 235 children were classified as Nutrition Grade B. In the case of the slow children the number whose nutritional status could be passed as Grade A was 24. This was 6.7% of the group. On the other hand, 22.1% (79 children) of these 357 slow children were of slightly subnormal nutrition, and were graded C. In addition, the three cases of bad nutrition (Grade D) were among the mentally slow children. The remainder of the group—that is, 215 children (70.3%)—were of normal nutrition, and were classified as B. It is of interest to note that the relative proportions of A and C children in the bright and slow groups are to all intents and purposes reversed. Over 20% of the bright children and some 6% of the dull children were Nutrition A; whereas Nutrition C cases among the slow children amounted to over 20% of the whole group, and the much smaller figure of 5.6% represents the Nutrition C cases among the children found to be bright.

(b) *Data for Boys and Girls Separately.*—Figures relating to sexes separately were prepared, and some interesting results were obtained. The data are set out in Table II. A total of 583 children (280 boys and 303 girls) from the group considered under (a), above, were reviewed.

TABLE II

Sex	Mental Activity	Nutrition Grades				Totals
		A	B	C	D	
Boys (280)	Bright	No. 28	72	8	0	108
		% 26.0	66.6	7.4	—	172
	Slow	No. 12	126	32	2	170
		% 7.0	73.2	18.6	1.2	100
Girls (303)	Bright	No. 57	125	8	0	190
		% 30.0	66.0	4.0	—	113
	Slow	No. 6	77	30	0	113
		% 5.3	68.1	26.6	—	—

With regard to the relative position of the sexes, 26% of the bright boys were Nutrition A and 7.4% were Nutrition C, whereas 30% of the bright girls were graded A and 4% graded C. Only 7% of the slow boys were included in Nutrition Grade A, and there were 18.6% in Grade C; whereas in the case of the girls 5.3% were Nutrition A, but the much higher proportion of 26.6% were graded C. In other words, of the bright children graded Nutrition A, 26% were boys and 30% were girls; that is, there was a 4% difference in favour of the girls. On the other hand, slow children graded Nutrition C amounted to 18.6% of the boys and to as many as 26.6% of the group of girls.

Discussion

A natural assumption from the data recorded above is that a correlation exists between nutrition and scholastic attainment. The evidence would appear also to indicate that a condition of

subnormal nutrition can constitute a serious handicap to the educational advancement of a child. A further inference from the data is that the mental activity of girls is even more closely related to their general physical state than is that of boys.

It may be contended that these deductions are not valid, inasmuch as parents of low intelligence not only beget children with a poor mental capacity but, in addition, cannot accord these children proper and sufficient care, with the result that malnutrition arises. In this way, it could be argued, the children who are mentally slow and who also suffer from malnutrition can be accounted for. Though this sequence is undoubtedly of not infrequent occurrence, yet only a comparatively small proportion of the cases in any one area could be accounted for on this basis. Moreover, the investigations of Corry Mann (already cited) are particularly significant in this connexion, in that he found that the boys in the group receiving supplementary milk, whose nutritional condition was thereby raised above that of the other groups, were more high-spirited and active. The same observation has been made in school dining centres provided for children with defective nutrition. The inference is that the malnourished child who has been labelled "slow" may, as a result of corrected dietetics and improved nutrition, attain to an ability to use his mental powers equivalent to that enjoyed by his better-nourished school-mate.

It is evident that further light on this aspect of the nutrition of children will be of value particularly to those interested in educational advancement.

Summary

The nutrition grades of 355 bright and 357 slow children were investigated. Of the bright children 28.2% were graded Nutrition A and 5.6% graded Nutrition C. Only 6.7% of the slow children were Grade A, while 22.1% were graded Nutrition C. The 3 instances of Grade D children were found in the slow group.

Of this group 583 members were arranged according to sex. Of the bright boys 26% were graded A and 7.4% were graded C, the corresponding figures for the girls being 30% and 4% respectively. In the case of the boys who were regarded as slow, 7% were Nutrition A and 18.6% were Nutrition C, whereas 5.3% of the girls in the slow category were Nutrition A and 26.6% were Nutrition C.

I am indebted to Dr John Stokoe, whose keen interest in matters connected with nutrition was a stimulus to inquiry.

KOILONYCHIA AND ITS RECOVERY IN CASES OF THYROTOXICOSIS

BY

LORNA COOKE, M.B., B.S.

AND

STELLA M. LUTY, M.B., B.S.

University College Hospital

So much emphasis has in recent years been thrown upon the relation of koilonychia to the anaemias, and especially to hypochromic anaemia, that it may be of value to record two cases and to comment that in neither was there any reason for supposing iron metabolism to be at fault.

Case 1

Mrs A., aged 69, was admitted to hospital on May 11, 1943, complaining of nervousness, palpitations, abdominal colic, and loss of weight of two years' duration, and of general tiredness and staring eyes for three months. On examination she was found to be emaciated, nervous, and very excitable. She had diffuse brown

pigmentation of the skin of the neck and of both upper eyelids. The prominence of her eyes was associated with conspicuous lid retraction on both sides—retraction so great that her eyes closed incompletely during sleep. The left cornea had a small abrasion. The thyroid was firm, both lobes and the isthmus being easily palpable and definitely enlarged. There was no retrosternal dullness. The outstretched hands showed a fine tremor; regular tachycardia of 100 to 110 persisted during the day and declined little at night. The cardiovascular system showed no abnormality apart from the tachycardia, and the other main systems seemed to be normal. The tongue was dry, brick-red, and fissured, but not sore. Her red blood cells numbered 4,800,000 and her haemoglobin was 81%. On admission the hands were persistently cold and blue—an unusual feature in thyrotoxicosis. The nails were brittle, conspicuously spoon-shaped, longitudinally striated, and cracked. She said that they had been in this state for about six months. The skin surrounding the nail, and especially at its base, was dry and scaly, and was encroaching upon the actual nail itself in an irregular manner. The free margin of the nail bed, instead of showing the normal clear-cut line of demarcation, was irregular.

Her stay in hospital was prolonged owing to the development of various complications. Soon after admission an acute respiratory infection was treated successfully with sulphathiazole. At that time the patient was having 30 minims of Lugol's iodine daily, and, at the end of the course, which coincided with the end of the respiratory infection, her pulse rate during the day was 80 to 90 and at night 80, with definite diminution of other thyrotoxic signs. During July she developed a large bed-sore and a suppurative parotitis, from which she recovered. Despite these infections her general health improved steadily, and it was noticed at the time that the condition of her nails was altering and that growth was now occurring normally, the scoop being pushed onwards (Fig. 3). The skin around the nails had become more normal and the pulp was more rounded. There was no further cracking of the nails. By August she had gained a stone in weight; her red blood cell count was 5,010,000 and Hb 98%. Her basal metabolic rate was +61%.

During September she developed another acute respiratory infection, which was treated with sulphathiazole, and also a severe conjunctivitis with corneal ulceration after a short course of thiourea. Nevertheless her general condition continued to improve steadily and her weight was increasing. Her pulse rate was in the region of 80 to 90 both day and night; her basal metabolic rate was +48%. On Oct. 1 her red cells were 4,690,000 and Hb 84%—values similar to those on admission. The normal growth of her nails continued, and as they grew they soon became perfectly formed and clear-cut at their margins, brittleness being lost (Fig. 4). She had gained nearly 2 stone more in weight.

Recovery of Nail Growth in Case I

The nails in Fig. 2 seem shorter than in Fig. 4. This apparent shortening was due to the skin clinging to the base of the nail and being carried onward with it. The extent of this skin encroachment could be ascertained by measuring from the V-shaped crease of skin to the nearest part of the exposed nail in Fig. 4 and transferring this measurement to Fig. 2. This is shown in the outlines of Fig. 1: the nail is at least as high up the finger as the dotted line of the right-hand tracing. It is important to fix this, the growing root of the nail, as accurately as possible if we are to ascertain the time at which growth

FIG. 1.—Case 1. Outline of middle finger on June 21 (right) and July 19 (left), showing the relative position of the proximal edge of the scoop, the root of the nail, and a V-shaped crease in the skin over the distal interphalangeal joint. Used to estimate the date at which formation of deformed nail ceased. Drawings made from Figs. 2 and 3.

changed from normal to abnormal. The position of the proximal margin of the scoop can be fixed relative to a given skin crease in Figs. 2 and 3 and, through this, to each other. In this middle finger it moved onwards by 5 mm. in four weeks; and the rate at which the scoop grew onward in the index finger was the same. In Fig. 2 the growing root of the nail lies about 9 mm. above the proximal margin of the scoop. It

would seem, therefore, that the arrest of abnormal growth must have occurred about seven weeks before Fig. 2 was taken—a date about April 1, or six weeks before the patient entered hospital. It may have been a little more or less. Special inquiry showed that the patient was continuously at home with her family between June, 1942, and May, 1943, and that during

FIG. 2.—Case I, June 21. Fingers 2, 3, and 4 of right hand, showing spoon-shaped nails. Note broken skin near root of nail—dry, and attached to nail and drawn onward by its growth.

FIG. 3.—Case I, July 19. The same fingers, showing growth of well-formed new nail; the scooped nail is growing off.

FIG. 4.—Case I, Nov 15. The same fingers, with well-formed nails.

that period, though ailing, she refused to see a doctor and took no medicine of any kind. No iron was given to her during her stay in hospital. It seems very difficult in these circumstances to associate the koilonychia with an iron deficiency, clearing up, as it would be necessary to suppose, during the end of the period of her home life. Moreover, her blood counts gave no encouragement to this idea.

The case serves to stress the importance of noticing in cases of koilonychia, when first seen, how close to the root of the nail the scoop comes, and the rate of nail growth, in attempting to correlate the scoop with clinical events. The factors bringing about faulty growth are not necessarily present when the deformity is first seen; they may have ceased to operate many weeks previously.

Case II

Mrs. B., aged 59, was admitted to hospital on Jan. 25, 1944, showing symptoms and signs of severe thyrotoxicosis. She complained of extreme nervousness for three years, and palpitation, staring eyes, and loss of weight for six months. On examination she was found to be thin, flushed, sweating, and very nervous. Her prominent eyes showed marked lid-retraction, up to 5 mm. of the sclerotic being exposed above the pupil and 3 mm. below. Her lids failed to shut during sleep. The thyroid showed a definite firm, even, pulsatile enlargement of the whole gland. The heart was slightly enlarged, and presented a regular tachycardia which decreased during sleep, a soft systolic apical murmur, and a accentuated aortic second sound. Her pulse was conspicuous water-hammer in character, and there was capillary pulsation. The blood pressure was 200/100 mm. Hg. A fine tremor shook the extended hands and all reflexes were brisk. The tongue was unmoist, fissured, and bright red, but not sore; there were sordes at the corners of the mouth.

The finger-nails were deformed and had been spoon-shaped, thin and brittle for about three months. The nails affected were those of both forefingers and, to a lesser extent, the right middle finger; the remaining nails were thin, brittle, and longitudinally striate but showed no scoop. The skin at the base of the nail was dry and adherent for 2 or 3 mm., producing apparent shortening of the nail as in the last case. The free nail margin was broken, and was irregular in thickness. The obvious concavity of the nail of the index finger extended up to the adherent skin.

Her basal metabolic rate two days after admission was +138 and her blood count showed 5 million red cells and 6,000 white cells which remained constant throughout her two months' stay in hospital. Weekly haemoglobin estimations showed a variation between 90 and 98%. A fractional test meal showed a normal acid curve.

For the first fortnight in hospital the patient was treated well in bed only. During this period her pulse rate subsided from 110 to 90 a minute with a slight general improvement. Thiouracil 1 g. three times a day was begun early in February. Five days later she developed severe conjunctivitis, which subsided in eleven days after the change to thiouracil 0.2 g. five times a day. Apart from this complication her general improvement continued steadily. She was shown by her calm behaviour and lack of apprehension, a fall in the pulse rate, and a conspicuous decrease in the exophthalmos and lid-retraction. Her basal metabolic rate decreased in five estimations steadily down to +15 and her weight increased by nearly a stone in two months. Her finger-nails gradually became normal; the brittleness disappeared, they became thicker and more unyielding, the dry-skin at the base of the nail receded, and the scoop gradually grew off.

The dose of thiouracil was reduced, the patient being discharged on April 1, 1944, on 0.2 g. daily.

Recovery of Nail Growth in Case II

In this case the nail of the index finger was at first concave over almost its whole surface. Some weeks elapsed before, as the nails began to grow properly, the upper margin of the scoop could be defined clearly. It was marked by staining it with a line of nitric acid, and its rate of onward movement was determined relative to the distal edge of the nail bed. On March 11 the distance was 8 mm., on the 25th it was 6 mm., on April 13 it was 4 mm., and on May 11 the line had just grown off. Thus the growth was regular, and at a rate of about 1 mm. a week. Now, the distance of the nitric acid mark from the root of the nail on March 20 was 6 mm.; and thus it may be calculated that normal growth began weeks earlier—namely, about a week after admission, a little more or less. Close inquiries showed that the patient had used nothing in her household duties, such as washing soda, that could be held to account for the condition of her nails on admission. She had taken no iron before admission, and was given none while in hospital.

Discussion

Discussion must be short because our observations on these two cases still leave the cause of koilonychia obscure. A brief inquiry into past records is enough to show that the spoon-shaped nail occurs under distinct circumstances, that it may be

hereditary or acquired, temporary or permanent and that it has been described in conjunction with various factors, local and general, thought to be of possible significance. Among other conditions we find thymomatosis named more than once (Heller, 1927, Rossegger, 1936), curiously, thyroid deficiency has also been blamed (Schonstein, 1929). Reference may be made to the useful general accounts of Heller (1927), Cipollaro (1930), and Rossegger (1936).

The other chief point we desire to stress is that in temporary onychchia, attempts to associate the nail change with any particular factor should take into account the abruptness with which the nail growth may lose its abnormality, while the change in the nail, which has been the result of earlier abnormal growth, may continue to be shown for many weeks or perhaps months. Thus it is clear that the presence of a concave surface does not mean that the process responsible for it is still active, indeed, when the concavity is at the distal end of the nail it is probable that the cause has been for a long time in abeyance—a fact to which Toegel (1937) draws attention in his case which followed brief exposure of the nails to benzene.

Our thanks are due to Sir Thomas Lewis for his assistance with these cases, and to Prof. H. P. Himsforth and Dr. Kenneth Harris of University College Hospital, for permission to use the case reports.

HISTOLOGICAL EFFECT OF INJECTION OF MEPACRINE (ATEBRIN) DIHYDROCHLORIDE*

BY

FRANK HAWKING, D.M.

(From the National Institute for Medical Research, London)

Recently a note was published (Hawking, 1943) concerning the histological effects produced by the intramuscular or subcutaneous injection of mepacrine methanesulphonate (atebrin musonate). However, the preparation most commonly issued for injection in the Army is the dihydrochloride (atebrine dihydrochloride). An investigation has therefore been made to see whether the effect of the dihydrochloride is significantly different from that of the methanesulphonate, and the opportunity has been taken to compare both of these preparations with quinine dihydrochloride, which is the preparation of quinine most commonly recommended for injection.

A 4% solution of quinine dihydrochloride has a reaction of pH 3.08. A 10% solution of mepacrine methanesulphonate has a reaction of pH 4.0 and one of 5%, pH 4.24. A 3.3% solution of mepacrine dihydrochloride has a reaction of pH 4.40. All these reactions were measured at 17°C. There is consequently no substantial difference in the acidities of the two solutions of mepacrine, and both are somewhat less acid than that of quinine dihydrochloride. The chief physical disadvantage of mepacrine dihydrochloride lies in its lower solubility. The methanesulphonate is soluble in water up to 33%, but the dihydrochloride only up to about 3.3% at 17°C. To obtain a 10% solution the mixture must be cautiously warmed to about 50°C (decomposition occurs on boiling), and then the solution is cooled to 37°C and injected without delay.

Technique

Mepacrine dihydrochloride (atebrine dihydrochloride, Wm-throps), 43 mg in 0.5 ccm of warm water, or mepacrine methanesulphonate (May and Baker), in equivalent amount (50 mg), was injected intramuscularly into the thigh or loin of rabbits, some injections were also made subcutaneously on the abdomen. Similar injections of quinine dihydrochloride (Howards), 20 mg in 0.5 ccm, were given to other rabbits in the previous work it had been found that the toxic action of 20 mg of quinine was approximately equal to that of 50 mg.

of mepacrine. The animals were killed at suitable intervals (1 to 10 days), the sites of injection were fixed in formalin and studied by the usual histological technique. Altogether mepacrine dihydrochloride was injected into 11 sites intramuscularly and 4 sites subcutaneously, and mepacrine methanesulphonate into 4 sites intramuscularly. Quinine dihydrochloride was injected into 7 sites intramuscularly and 3 sites subcutaneously.

A parallel series of observations were made with rats. 43 mg of mepacrine dihydrochloride in 0.3 ccm of water was injected intramuscularly into the thigh and subcutaneously on the abdomen, respectively, in 8 sites of each type, 5 mg of mepacrine methanesulphonate was injected intramuscularly and subcutaneously into 3 sites of each type, and quinine dihydrochloride 10 mg in 0.3 ccm of water was similarly injected into 8 sites of each kind. The dose of quinine was twice that of the mepacrine, since the therapeutic dose of quinine (0.6 g) is usually at least twice that of mepacrine (0.3 g).

Experimental Results

Naked eye Appearances.—When mepacrine dihydrochloride was injected into the lumbar muscles of rabbits a fusiform lesion was produced about 4 cm in the long axis of the muscle, by 2 by 1 cm. The lesion, on section, was dark red surrounded by a narrow yellow or whitish zone (leucocytes). In the thigh the connective tissues along the sciatic nerve were usually swollen, and often there were haemorrhagic patches in the adjacent muscles, but the appearances were less regular than those in the loin. The thigh is much less suitable than the loin for observing the effects of intramuscular injection, since so many fascial planes are present that the injected material is deposited chiefly in the connective-tissue spaces between the muscles rather than inside the muscles. In the thigh of rats there was occasionally some yellowness and oedema of the connective tissue around the chief vessels and nerves, and in one animal killed after seven days there was contracture of the muscles, but on the whole the macroscopical changes were inconspicuous. The lesions produced by mepacrine methanesulphonate were indistinguishable from those described above and so were those produced by quinine dihydrochloride (apart from the absence of any yellow staining).

When mepacrine dihydrochloride or methanesulphonate was injected subcutaneously it caused great thickening of the skin extending 4 to 9 cm and due to yellow gelatinous oedema of the deep connective tissue, later a hard necrotic scab was formed. With quinine dihydrochloride the swelling was less marked and there was no yellowness.

Since mepacrine is strongly fluorescent some of the animals were examined under ultra violet light, diffuse yellow fluorescence was seen in the tissues around the site of injection, especially subcutaneously, but the distribution could not be definitely mapped out by this method.

Microscopical Appearances.—When mepacrine dihydrochloride was injected into the compact muscles of the loin an area of coagulative necrosis with haemorrhage was produced, as described above. A short distance inside the margin of this area there was a zone of disintegrated leucocytes (seen macroscopically as a yellow band), but the necrosis extended outside this zone, and the demarcation between necrotic and living muscle was initially indistinct. After some days there was a second cellular reaction at the demarcation line, and in 10 days a definite layer of granulation tissue was formed in which were embedded shrunken muscle fibres, a few giant cells, and new collagen. In the looser tissues of the thigh the main reaction occurred in the intermuscular connective tissue, which was initially greatly distended with fluid and infiltrated with polymorphs and mononuclears. Haemorrhages and collections of albuminous exudate were also present, and most of the tissue appeared necrotic. The superficial layers of the adjacent muscles were necrotic to a variable depth and the connective tissue inside the muscle often contained fluid and leucocytes, haemorrhage was sometimes present. After from 3 to 7 days some of the necrotic muscle fibres became calcified, and the necrotic areas were separated from the healthy tissue by a zone of young granulation tissue containing many mononuclear cells. In the thighs of rats the appearances were similar. The lesions caused by mepacrine dihydrochloride were indistinguishable

* Report to the Malana Committee of the Medical Research Council.

able from those caused by the methanesulphonate, which were described in the previous note and which were confirmed in the present work. The lesions produced by quinine dihydrochloride could not be definitely distinguished from those due to mepacrine; at the margin between the surviving and the swollen coagulated muscle fibres, groups of shrunken basophilic fibres were found, but these also occurred to a less extent in some of the sections of tissue with mepacrine. The necrosis produced in the loin by 20 mg. of quinine was not quite so extensive as that produced by 43 or 50 mg. of mepacrine, but that produced by 10 mg. of quinine in the thigh of rats was not conspicuously greater than that due to 4.3 or 5 mg. of mepacrine.

When mepacrine dihydrochloride or methanesulphonate was injected subcutaneously into rabbits or rats it caused necrosis of the epidermis, subcutaneous layer of muscle, deep connective tissue, and part of the muscle of the abdominal wall. The deep connective tissue was greatly distended with fluid and contained variable numbers of cells; at first these were principally polymorphs, but after a few days mononuclears predominated. By seven days the necrotic area was surrounded by a zone of granulation tissue. With subcutaneous injections of quinine dihydrochloride (20 mg.) the oedema, necrosis, and cell infiltrations were somewhat less extensive than with mepacrine (43 mg.). In rats 10 mg. of quinine caused somewhat less swelling and cell infiltration than 4.3 mg. of mepacrine, but the necrosis was equally extensive.

Pieces of tissue injected with mepacrine were fixed in formalin, cut as frozen sections, and examined on a fluorescence microscope. The necrotic muscle fibres shone bright yellow; connective tissue and the outer coat of blood vessels from the areas of necrosis shone a little; other tissues were hardly visible.

Discussion

From the above experiments it is clear that there is no difference in the local toxicity of mepacrine dihydrochloride and that of mepacrine methanesulphonate, although methanesulphonate is more convenient to use owing to its greater solubility. The necrosis caused by mepacrine is indistinguishable in type from that caused by quinine dihydrochloride. The relative amounts of necrosis which will be produced in man by therapeutic injection of the two compounds are difficult to predict from animal experiments, since the size of the lesion is not proportional to the dose. As described above, when given by intramuscular injection 43 mg. of mepacrine caused somewhat more necrosis than 20 mg. of quinine; but the necrosis produced by 4.3 mg. of mepacrine injected into the thigh of rats was not conspicuously less than that produced by 10 mg. of quinine. When injected subcutaneously into rats, 4.3 mg. of mepacrine produced more swelling and cellular reaction than 10 mg. of quinine did, but the necrosis was no more extensive. Since the therapeutic dose of mepacrine by injection is only one-half to one-third that of quinine, it is probable that the necrosis produced by intramuscular injection of mepacrine will be less extensive than that produced by quinine; and this conclusion agrees with the clinical reports reviewed in the previous paper. Nevertheless it is clear that the local damage produced by intramuscular injections of mepacrine is far from negligible.

Mepacrine given by intramuscular injection is rapidly absorbed. As concluded in the previous note, the damage caused is not sufficient to contraindicate its use if the patient's life or health is in danger, but it is great enough to make this method of administration inadvisable if the patient can possibly take the compound by mouth. Intravenous injection of mepacrine has been found in American experience to be dangerous to life, and its use has been condemned. Subcutaneous injection of mepacrine is not recommended under any circumstances; it was included in the present experiments for technical reasons as being a sensitive method of displaying the effect of injected substances upon the tissues.

Summary

The histological effect of intramuscular and subcutaneous injection of mepacrine dihydrochloride (atabrine dihydrochloride) in rabbits and rats was compared with those of mepacrine methanesulphonate and of quinine dihydrochloride. Mepacrine dihydrochloride has the

same acidity in solution as the methanesulphonate, but it is less soluble (solubility 1 : 30 at room temperature) and therefore slightly less convenient to use; the local toxicities of the two compounds are indistinguishable one from another. The injection of therapeutic doses of mepacrine produces necrosis of the tissues around the site of injection; this necrosis is identical in type with that produced by the injection of therapeutic doses of quinine dihydrochloride, but it is probably somewhat less extensive.

It is considered that mepacrine dihydrochloride is suitable for administration by intramuscular injection, although it is less convenient than mepacrine methanesulphonate; but this route should not be used if it is practicable to give the compound by mouth. Mepacrine should not be given by subcutaneous or intravenous injection.

Grateful acknowledgments are due to Mr. F. J. Higginson for the histological preparations.

STERILIZATION OF THE SKIN BY COLOURLESS FLAVINE (5-AMINO-ACRIDINE)

BY

VICTOR BONNEY, M.S., M.D., B.Sc., F.R.C.S., F.R.A.C.S.

AND

H. SANDEMAN ALLEN, O.B.E., M.B., B.Ch., F.R.C.S.

In the *British Medical Journal* of May 18, 1918 (p. 562), one of us (V.B.), in conjunction with Carl Browning, introduced a new antiseptic solution which we named violet-green (sometimes known as "Bonney's blue"), for sterilizing the skin; this, because it was entirely non-irritant, could be applied in strength for many hours without harming the skin. The bacteriological investigations then undertaken showed that, to sterilize the skin completely, the time over which the antiseptic can be applied is even more important than its absolute bactericidal power; or, in other words, more effect is obtained from a bactericide of moderate potency which can be applied for a long time than from one whose potency is of a very high order but which, on account of its effect on the skin, can be applied for only a very short time. Violet-green, however, combined high bactericidal power with non-irritancy and therefore amply filled the bill, and since its introduction it has been extensively used not only in surgery and obstetrics but in dermatology as well. It has, however, been objected against it that it intensely stains the bed-linen of the patient and the hands of the nurses. This is true, particularly when one is unaccustomed to its use. On the other hand, applied to the vagina, the staining is a great advantage when—as, for instance, in total hysterectomy—that canal has to be opened from above, for the deep coloration defines it very clearly.

The recent production of colourless flavine* (5-amino-acridine) suggested to one of us (V.B.) the making of a solution similar to violet-green, but containing, instead of 1% of equal parts of crystal violet and brilliant green, 1% of colourless flavine, in the same solvent—namely, equal parts of rectified spirit and water. The presence of water appears to be, in general, a necessity for the full development of antiseptic action; and, in connexion with that requirement and the pale yellow powder with which this paper is concerned, an analogy may be drawn between it and another and very homely yellow powder, called mustard, which, pungent and tear-provoking when mixed with water, can yet as a dry powder be placed on the tongue without any taste or discomfort. The spirit is added to counteract the grease of the skin, which checks a purely watery solution from spreading itself and delays absorption.

It should be noted that colourless flavine is not really colourless, but has a pale lemon tint, which just stains sufficiently to show the limits of its application—a very desirable property in any antiseptic used for the skin. To make the solution, the flavine is first dissolved in the water and then the spirit is added.

Method of Application.—The skin of the operation area, having undergone the usual cleansing, is first painted with the solution and then covered with a piece of double-thickness lint.

* Made by Glaxo Laboratories, Ltd.

soaked to capacity in the solution; this in turn is covered by a sheet of waterproof material and fixed on by a binder or bandage. The compress is applied 6 hours before the operation, and is removed on the operating table.

Bacteriological Tests.—These were carried out on 38 consecutive cases prepared for abdominal section. In each case, when the compress was removed, a platinum loop was made to streak the prepared skin surface and was then streaked on the surface of human blood-agar in a Petri dish. Four such streaks were made from different parts of the prepared area and were streaked on four different areas of the plate. As a control, four similar streaks were taken from an area of skin just outside the prepared area and streaked on the surface of another blood-agar plate. Multiple streaks enable a judgment to be made between growth indicating permanent diffuse infection and growth indicating chance contamination or loop-holes in the preparation.

Results

Prepared Areas.—Of the 38 plates from the 38 prepared areas, 29 showed no growth at the end of four days' incubation and 9 showed growth. Of these 9, one exhibited it on 3 of the 4 streaks, four on 2 of the 4 streaks, and four on 1 streak only. No plate had growth on all 4 streaks. Moreover, the bacterial colonies were few and isolated, except on the plate which showed growth on 3 streaks, and in this case there were other reasons to believe that the preparation had not been carried out thoroughly. As regards the growth on the other plates, these too were probably due to imperfect preparation, though in lesser degree. The effect of the antiseptic, however, is best displayed by comparing the number of sterile streaks with those not sterile; for of the total 152 streaks made from the prepared areas only 15 showed growth. From these the following organisms were identified: *Staph. aureus haemolyticus*, from 9 streaks; non-haemolytic *Staph. aureus*, from 1 streak; and *Staph. albus*, from 9 streaks.

Controls from Unprepared Areas.—All the 38 plates from the 38 unprepared areas showed growth at the end of four days' incubation. Growth occurred on all four streaks in 36 of them, and on three out of four streaks in 2. Counting the number of streaks instead of the number of plates, it is seen that of the 152 streaks made from the unprepared areas 150 showed growth and only 2 remained sterile. The growths in most cases were profuse, and the following organisms were identified: *Staph. aureus haemolyticus*, from 118 streaks; non-haemolytic *Staph. aureus*, from 10 streaks; *Staph. albus haemolyticus*, from 17 streaks; non-haemolytic *Staph. albus*, from 86 streaks; *Str. haemolyticus*, from 1 streak; non-haemolytic streptococcus, from 16 streaks; *Staph. citreus*, from 4 streaks; and diphtheroid organisms, from 30 streaks.

In addition to these tests one of us (S.A.), in order to ascertain the depth to which the antiseptic effect reached, on 13 occasions took cultures from the cut edge of the skin after the incision was made. In 12 cases no growth occurred, but in the remaining case *Staph. aureus haemolyticus* grew. This was the same case in which 3 of the 4 streaks taken from the prepared area showed growth and in which there was a strong suspicion that the area had not been properly prepared.

Discussion

It is to be noted that *Staph. aureus haemolyticus* was by far the commonest organism recovered. It occurred in 35 of the total of 38 plates taken from the unprepared areas, and the frequency on the skin of an organism so potent for mischief gives all surgeons cause to think furiously. The danger to surgical achievement which lurked in unsterilized skin, and the need to abolish it, were taught by the great thinker Lister. Then, in reaction, arose the soap-and-water school, headed by Lawson Tait, which asserted that simple cleanliness was enough: that good surgical results can be so attained is true, for healthy tissues have strong resisting powers. Later still, another school of thought emerged which, recognizing the difficulty of completely sterilizing the skin, employed as the chief line of defence cotton or rubber sheeting to cut out the skin—and this remains the usual practice to-day. But, although the soap-and-water school as such has disappeared, there remain some persons who, believing that swabbing with an antiseptic immediately before the operation sterilizes the skin,

unknowingly depend on what its adherents depended on. The bacteriological investigations carried out in connexion with violet-green showed quite conclusively that such brief applications do not effect sterility, though they do enfeeble the organisms so that growth on the agar plate is delayed as compared with that on the controls. Iodine is the best of these perfunctory applications, because it has superior power of penetrating organic material—a quality made use of in the sterilizing of catgut.

Organisms entrenched in the skin are very stout enemies, and to knock them out a vigorous and, above all, prolonged attack is required. Those who do not appreciate this fact ascribe the satisfactory healing of the wounds they make to the perfunctory measures they have taken, though in reality they owe it to that natural tissue resistance which enabled the soap-and-water school to make good its claim. But every now and then the enemy gains a foothold, and failure of the wound to heal kindly leaves the operative result something less than perfect and the surgeon with his pride hurt—and sometimes worse things happen. Surgical success depends on so many factors that the share taken by rigid antisepsis cannot be assessed in figures, though it can be perceived by anyone who studies attentively over a number of years the results of different surgeons practising different degrees of antisepticity. But whatever the share is, everyone must agree that operative infection arising from the skin is a theoretical possibility, and it is the duty of a surgeon to close all doors against all possibilities, theoretical or otherwise. To ensure, as far as may be, initial sterility of the skin should be the first line of defence against infection from the skin, and sheeting the second line, in case the first fails. For those who object to violet-green on the score of staining, the solution we describe, if used in the manner set forth, efficiently and inoffensively sterilizes the skin.

Our thanks are due to the pathological department of Cheltenham Hospital for the work it has done for us.

PITUITARY CACHEXIA TREATED WITH CORTICOTROPHIC HORMONE

BY

R. E. HEMPHILL, M.D., D.P.M.

Medical Superintendent, Bristol Mental Hospital

AND

MAX REISS, M.D., D.Sc. Prague

Department of Endocrinology, Burden Neurological Institute

Panhypopituitarism, not the result of pituitary necrosis following pregnancy, has been regarded as a clinical entity (Fraser *et al.*, 1941). We (Hemphill and Reiss, 1940, 1942) have described cases in which severe melancholic depression associated with clinical pituitary cachexia—namely, emaciation, asthenia, loss of hair, desiccated skin, and low output of 17-ketosteroids—developed after the menopause. Although there was usually evidence of polyglandular insufficiency, where the skin was dry, hair brittle, and 17-ketosteroids low with subjective complaints that the "bowels did not operate," adrenocortical failure seemed the most important endocrine disturbance. On this hypothesis a number of such cases have been treated with corticotrophic hormone. This treatment was on the whole promising, and early results have been recorded already (Hemphill and Reiss, 1940, 1942). The case described below showed such extreme emaciation that the picture was that of advanced Simmonds's disease. Complete physical recovery followed treatment with two courses of corticotrophic hormone. The mental condition cleared up some time later.

Case Record

A woman aged 41 was admitted to the Bristol Mental Hospital on Dec. 21, 1940. She was married, but had never been pregnant. There was no history of antecedent mental or physical illness. The menses ceased abruptly at the age of 39 without hot flushes or other subjective menopausal disturbances. About six months before admission she became depressed, lost appetite, and imagined that her viscera were deranged and the bowels "stopped up"; she attempted suicide. This was the mental condition on admission. Physically she was thin, weak, and frail-looking; height 5 ft. 6 in.,

weight 6 st. 3 lb. The skin was sallow, with an extremely dry "desiccated" texture; sweating was entirely absent, and there was a marked sensitivity to cold. The blood pressure was 90/60 mm. Hg. There were no respiratory, cardiac, or renal abnormalities. The breasts and mons veneris were atrophied; the hair of the head was brittle and lustreless, that of the pubis and axillae scanty; muscle bulk was very much reduced. There was no assayable output of gonadotrophic, corticotrophic (method of Reiss *et al.*, 1936), or thyrotrophic (method of Heyl and Laqueur, 1935) hormones in the total urine of 96 hours; the output of 17-ketosteroids was 2.6 mg. per 24 hours. The patient (Figs. 1 and 2) displayed none of the

delusions of alimentary malfunction and gain in appetite, there was at first little mental change. Even the posture and expression were unaltered in spite of the improvement in physical state. There has been a change recently. She is now less retarded and seems to be emerging from the depressive state.

FIG. 1

FIG. 2

FIG. 4

FIG. 5

restless activity seen in anorexia nervosa. There was a low concentration of intercellular water, as shown by the diurnal electrical resistance of the skin, which, normally now and steady after the menopause (Hemphill, 1942), was high and fluctuated widely. Attempts at fattening failed in the next ten months; the weight dropped to 4 st. 11 lb.

Corticotrophic hormone, 40 sudanophobic units daily for 24 days, was administered. There was an immediate improvement in appetite and some return of the sense of well-being. The desiccated appearance of the skin had gone, and within four days the electrical resistance fell to the normal low level, at which it remained steadily. Two months later a further course of 14 daily injections of 25 units was given. The weight rose steadily and has continued to do so (Fig. 3). It is now two years since any hormone treatment has been

Discussion

In this case the physical condition was that of pituitary cachexia, and conformed closely to the picture of Simmonds' disease. Although there was no history of antecedent pregnancy the emaciation and asthenia, dry skin, loss of hair, at subnormal output of anterior pituitary hormones may be attributed fairly to adrenocortical insufficiency secondary hypopituitarism. This was corrected by treatment with corticotrophic hormone. Improved adrenal performance would be accompanied by improved water and fat storage with normal salt retention, and therefore better metabolism of alimentary function. Objective evidence that this took place was provided by the gain in weight and strength, loss of the desiccated quality of the skin, restoration of the normal electrical resistance behaviour, rise in output of 17-ketosteroids, and loss of delusions of alimentary inadequacy, which, as we believe, are a secondary derivation of the physical illness. The mechanism of cure was at first replacement therapy. Either atrophy or suppression of function of the adrenal cortex for want of trophic stimulation produced at least a large part of the clinical picture. Stimulation of the adrenal cortex by injected corticotrophic principle of the pituitary at first corrected the deficiency. It is reasonable to suppose that with an approach to normal water and fat metabolism other endocrines behaved in a more normal way, so that to some extent their insufficiency was adjusted. That the patient was able to remain well and even to improve further when corticotrophic hormone was no longer administered indicates that once the anterior-pituitary-peripheral-endocrine system was set in motion, there being no destruction of anterior pituitary substance, it could continue to function satisfactorily without aid.

given, but the improvement has been maintained. The breasts have developed and there has been a normal deposition of fat and restoration of hair loss (Figs. 4 and 5). Menses have not returned, and the vaginal smear, as before treatment, is of the post-menopausal atrophic type. The 17-ketosteroids rose to 8.3 and later improved to 10 mg per 24 hours. Apart from an immediate loss of the

FIG. 3

It is believed that menopausal symptoms in many women are due to a temporary rise in gonadotrophic hormone output from hyperactivity of the anterior pituitary (Nathanson *et al.*, 1940). We have noticed in this and similar cases that the menopause came abruptly and there was a complete absence of menopausal symptoms. Assays in such cases showed a very

low or a negligible output of gonadotrophic hormone. This suggests that in this type of case there is a sudden functional reduction in pituitary activity to be followed later by the physical symptoms of hypopituitarism. The suggestion that the picture of pituitary cachexia without structural changes in the pituitary itself can follow the menopause is supported by the resumption of normal pituitary function observed in this case after treatment. The physiological properties of corticotrophic hormone have been studied in hypophysectomized rats. It is known that sugar storage is much reduced after hypophysectomy, for the combustion of fed sugar is much higher than in normal animals. This condition has been corrected by corticotrophic hormone (Reiss *et al.*, 1938). The cholesterol and fat content in hypophysectomized rats can also be increased by corticotrophic hormone (Reiss *et al.*, 1937). No doubt there were comparable actions in the case we have described.

Summary

A case of clinical pituitary cachexia in a nulliparous woman has been described. Clinical and hormone studies indicated extreme hypopituitarism. Treatment with corticotrophic hormone resulted in complete restoration of weight and cosmetic features. This was not a case of anorexia nervosa. The psychotic depression was not relieved until a considerable time after physical improvement was complete. The origin of this condition has been discussed.

Medical Memoranda

Effect on the Nutrition of School-children of adding Vitamins and Minerals to the Diet

The purpose of this experiment was to discover if the addition of minerals and vitamins to the diet of school-children would make them gain weight at an increased rate.

THE INVESTIGATION

The experiment was carried out between Oct., 1940, and May, 1941, in an industrial area on the south bank of the Thames. For three months 300 children were weighed fortnightly, half of them were then given vitamin supplements for five days a week for three months, and the fortnightly weighings were continued. The ascorbic acid and vitamin B₁ contents of the urine of the "vitamin children" were determined before and after the administration of the supplement, a few vitamin A tests were performed with the photometer. The incidence of colds in the groups was recorded.

The daily supplement given contained 360 mg. of calcium, 552 mg. of phosphorus, 4,000 units of vitamin A, 300 units of vitamin D, 200 units of vitamin B₁, 12 mg. of available iron, 20 mg. of ascorbic acid, and some trace of minerals.

Results.—The average gain in weight of the vitamin children was no greater than that of the controls. The initial urinary estimations suggested that the intake of vitamin B₁ and of ascorbic acid was low, but there was no gross deficiency. Very few of the children showed increased excretion of the vitamins at the end of the experiment (It should be noted, however, that the vitamins were estimated in single specimens of urine.) The few photometer tests carried out did not show any marked deficiency at either the beginning or the end of the experiment, there was no difference between the two groups in incidence of colds.

DISCUSSION

The experiment, though limited in scope, seems worth reporting, for it was carried out earlier than the other vitamin-feeding tests, in a different part of the country, and minerals as well as vitamins were added to the diet.

The fact that the children did not gain weight at an increased rate while having the supplement may be explained in several ways. The tablets might not have been taken regularly, no vitamin shortage may have been present initially, or a vitamin deficiency may have been present which was so severe that the supplements were not adequate to deal with it. Or a moderate deficiency might have existed, but vitamins given in tablets might not have been so effective as they would have been if

given in fruit and vegetable juices. Or a moderate deficiency might have been present, capable of being dealt with by the supplements but accompanied by a deficiency either of first-class protein or of calories. Finally, the children might have been on optimum diets at the beginning of the experiment, and so could not be expected to gain at an increased rate.

There is not space to discuss these points fully. It seems probable that a mild vitamin deficiency existed, accompanied by a shortage of protein. It is possible that the vitamin tablets were not so effective as fruit and vegetable vitamins; it is probable that the children were not on optimal diets. (This last conclusion was arrived at by comparing the average weights of the boys who took the supplements with those of public-school boys.)

This experiment merely corroborates the findings of several workers in this field. Feeding of vitamins in tablets to school-children has had no appreciable effect on weight.

It would be interesting to see the effect on the weight of English school-children of the diet recommended by Brown and Robertson of Toronto as late as 1942. Who could help thriving on food such as the following. (1) A quart of milk daily (32 oz.)? (2) One generous serving of orange, grape-fruit, tomato, or raw cabbage, fruit at another meal, and two vegetables besides potato. (3) One serving of whole-grain cereal with wheat germ. (4) One serving or more of meat, eggs, fish, or fowl, with eggs three or four times a week, and liver or kidney once a week. (5) One regular dose of a good source of vitamin D during at least the six colder months of the year.

I should like to thank Vitamins Ltd. for supplying the tablets free of cost, and also all those who helped me with the experiment.

CECILE ASHER, M.D., M.R.C.P.,

Assistant M.O.H. to the Borough of Finsbury (formerly of Eritch).

Herpes Simplex Corneae in Malaria

Herpes simplex corneae is said to be the commonest ocular complications in malaria (Duke Elder, 1943). Low and Fairley (1941) state that iritis, retinal haemorrhage, and optic neuritis also sometimes occur. In a series of 4,000 European cases of malaria in West Africa herpes simplex corneae was the only ocular complication noted. Rings of the malignant tertian form of malaria were demonstrable in 35% of the cases. The remainder were diagnosed on clinical grounds as malignant tertian malaria. Corneal lesions developed in the following four cases.

CASE HISTORIES

Case 1.—This patient had three attacks of malaria. In the second attack he developed herpes of the lip on the second day and herpes of the right cornea on the eighth day. The eye was red and painful and corneal sensitivity was diminished. Staining showed multiple fissures in the corneal epithelium. The eye settled in ten days, leaving one nebula. After the third attack, two months later, the nebula had faded and sensitivity had returned to normal.

Cases 2 and 3.—One patient developed herpes simplex corneae in his first and fourth of five attacks of malaria. Dendritic ulcer followed in both instances. The first herpes developed on the sixteenth day, in the left eye, and was rapidly followed by a spreading dendritic ulcer. Treated with atropine and heat, the ulcer healed in 40 days, leaving a scar. The second herpes occurred on the seventh day of a later attack of malaria. A dendritic ulcer, in the shape of a lion rampant, developed on the site of the old scar, and spread rapidly. The whole corneal epithelium was removed with a strong solution of iodine (7% iodine and 5% potassium iodide in alcohol solution). The eye improved rapidly and was quiet within ten days, leaving the old scar and impaired corneal sensitivity. Another attack of malaria with herpes labialis three months later provoked no eye complications, although the corneal sensitivity was still impaired. The original corneal scar was then less pronounced.

Case 4.—This patient developed herpes of the left cornea on the tenth day of his second attack of malaria. A small ulcer formed near the limbus, which was slow to heal. Treated with atropine and heat, it became vascularized and quiet in five weeks.

COMMENT

In four cases of unocular herpes simplex corneae among 4,000 cases of malignant tertian malaria corneal lesions occurred between the seventh and the sixteenth day of illness. The best result followed removal of the corneal epithelium with strong iodine solution.

Reviews

PRINCIPLES OF NUTRITION

Nutrition and National Health; being the Cantor Lectures delivered before the Royal Society of Arts, 1936. By Major-General Sir Robert McCarrison, M.D. (Pp. 75; illustrated. 6s.) London: Faber and Faber, 1944.

Rose's Foundations of Nutrition. Fourth edition. Revised by Grace MacLeod, Ph.D., and Clara Mac Taylor, Ph.D. (Pp. 594, including an appendix of 190 pages; illustrated. 53.75s.) New York: The Macmillan Company, 1944.

What was sound teaching in nutrition in 1936 is still sound to-day, and the re-publication of Sir Robert McCarrison's lectures is welcomed. In them he has given a short account of his experiences in the relation of diet to health and disease in India, supported mostly by his own experimental work on rats. He has brought his knowledge of certain seriously deficient Indian diets to bear on the diets of the British people. With a breadth of view which is very stimulating he is able to show that the effects of partial deficiencies may be at least as serious (e.g., in lack of resistance to infection) as those of certain more nearly total deficiencies (e.g., in rickets). His teaching is always constructive. He shows how poor diets may be made good, simply and cheaply, and he pleads for wider education (not only of the poorer classes) on the constitution of good healthy diets, and particularly on the value of whole wheat, milk, and vegetables. The book will be read with pleasurable appreciation by many people, and not least by those who, by now, may be getting rather tired of the "textbook" kind of writing on the subject of nutrition.

Rose's Foundations of Nutrition has been largely revised by two of Prof. Rose's friends who had worked in the same department with her for many years, and with whom she had discussed new arrangements and additions to her book for its next edition. The new arrangements are the result of further experience gained in teaching the principles and practice of nutrition to students with many different backgrounds. The additions are the result of the ever-increasing volume of research work which is being carried out in laboratories all over the world, and of the increasing interest in and even legislation for the practical application of the findings to human dietaries. The more recently discovered vitamins—riboflavin, nicotinic acid, pyridoxine, pantothenic acid, para-aminobenzoic acid, biotin, choline, folic acid, inositol, vitamins K, M, and P, the grass-juice factor, and the milk factor—are treated as fully as present knowledge and the scope of the book demand. Daily requirements of calories, protein, calcium, iron, vitamins A, B₁, C, D, riboflavin, and nicotinic acid are accepted in the amounts proposed by the Food and Nutrition Board of the National Research Council, U.S.A. Particular foods—e.g., foods derived from grain, vegetables and fruits, eggs, cheese, nuts, meat and other flesh foods, fats, sugars and other sweets—are each considered as a whole. The construction of adequate diets for adults, mothers, babies, pre-school and kindergarten children are treated in a capable and practical manner, with enough evidence given in an interesting form to make the reader see how well worth while it is to give the thought and trouble necessary to give an adequate diet for human beings of all ages and ranks of life.

A YEARBOOK OF HEALTH INSTRUCTION

Health Instruction Yearbook. Compiled by Oliver E. Byrd, Ed.D. (Pp. 308, 18s. 6d.) California: Stanford University Press; London: Oxford University Press.

In order to improve health education in American schools and institutions of higher learning Prof. Oliver E. Byrd, director of health education at Stanford University, has published a comprehensive yearbook, the first of an intended annual series. It is designed for the use of teachers of hygiene, school nurses, school administrators, students, and others who desire to know of the developments in the field of health, and it seems extremely suitable for the purpose. It includes an enormous mass of reliable and up-to-date information, derived mostly from American sources but including many references to experiences in Britain and other countries. Some of its

chapters are so full of facts and figures as to be slightly indigestible for the general reader, but the information should prove useful for reference.

Among the twenty chapters will be found a lengthy one on nutrition and health. This includes an interesting sidelight on the extraordinary variety of peoples now incorporated in the British Army. For them no fewer than 130 different ration scales of food have to be provided. Though we in this country may think that ration cards are a worry, we must pity the average Swede, who has at least 25 cards in current use, and has to read a sort of stock market report whenever he goes out to shop. In the chapter on exercise and mechanics we read that of the first two million men examined in America for military service, 50% had to be rejected, almost all of them for physical and mental defects. The chapter on mental health and disease records that the Nazis at first tried to whip their soldiers into shape by brutality, punishment, and other rough treatment, but that on the advice of their psychologists they found it advantageous to make military life attractive, to assist instead of to punish, and to play up the group spirit. Officers were required to be informal with their men in contrast to the old Prussian concept. The long chapter on infection and immunity deals rather fully with malaria and venereal disease, while there are shorter chapters on habit-forming substances and on safety (especially traffic accidents). From the chapter on family health it is surprising to learn that over 40% of the native Americans living in the United States (in 1940) were not registered at the time of birth. A long chapter on school health is followed by shorter ones on occupational health and community health services. In the last chapter, on trends and probabilities, it is stated that a Bill was introduced in the Senate in 1943 which proposes a single unified system of national social insurance. It resembles the Beveridge plan in many respects. Another item of information relates to a scheme which is said to be unique in municipal history. The City of New York has contracted to pay the Public Health Research Institute \$100,000 a year for fundamental medical research and investigation.

A HANDBOOK ON V.D.

Handbook of Diagnosis and Treatment of Venereal Diseases. By A. E. W. McLachlan, M.B., Ch.B., D.P.H., F.R.S. Ed. (Pp. 364; illustrated. 15s., plus 7d. postage.) Edinburgh: E. and S. Livingstone, 1944.

When an author sets himself the task of writing a book on a medical subject he should, like an orator or a preacher, have two main objects in view: first, to gain the attention of those whom he is addressing, and, secondly, to hold it. Dr. McLachlan in his *Handbook of Diagnosis and Treatment of Venereal Diseases* certainly succeeds in the former. This is an attractive little book of convenient size, crammed with useful information and adorned with numerous figures—many of them beautifully reproduced in colour; in fact it would be hard to find anywhere coloured plates which depict the lesions of syphilis more faithfully. It is in regard to the second desideratum that we find him less successful. The style is ponderous, not to say pedantic, tautology is frequent, and long words are used where simple short ones would meet the case.

The essential points in the diagnosis of syphilis, and the signs of the disease in its various stages, are set out with commendable clarity, and the treatment of the disease is in keeping with modern British teaching; that is to say, the keeping with modern British teaching; that is to say, the concurrent-intermittent system, using neoarsphenamine and bis-muth, is the one recommended. Gonorrhoea is dealt with at some length, and the sulphonamides are skilfully handled—not given in inadequate doses, as occurs only too commonly nowadays. Apparently the subject-matter of this book had been in hand for some time before publication, since, of the various recent intensive methods of treating syphilis, only the five-day method is mentioned, and the word "penicillin" does not occur in connexion with the treatment of either gonorrhoea or syphilis. Sulphonamide-resistant gonorrhoea is rearing its ugly head more and more, and often taxes the ingenuity of the experienced venereologist, to say nothing of the general practitioner. A fuller section on this subject would have added greatly to the value of the book. Besides sections on syphilis, gonorrhoea, and chancroid there is a chapter on urethroscopy which is particularly good, and, finally, one on other conditions

ANTITOXIC AND ANTIBACTERIAL SERA

Diphtheria antitoxin

Tetanus antitoxin

Gas gangrene antitoxin (perfringens)

Gas gangrene antitoxin (polyvalent)

Tetanus-gas gangrene antitoxin

Anti-dysentery serum (polyvalent)

Streptococcus (scarlatina) antitoxin

Anti-streptococcus serum (polyvalent)

Exhaustive tests ensure that all these products satisfy high standards of purity

Iron and infant feeding

**M.O.F. PROVIDES IRON
IN AN EASILY ASSIMILABLE
FORM**

*Applications for supplies for Clinical Tests
should be made to A. & R. Scott Ltd., Dietetic Dept.,
20 Brook House, Park Lane, London, W.1*

PREPARED BY A. AND R. SCOTT LTD., WEST MILLS, COLINTON, MIDLOTHIAN, SCOTLAND.

M.O.F. is now fortified by the addition of calcium, phosphorus, iron and vitamin D in their proper proportions. Iron is added in minimum quantity to assure an adequate intake, and in such a form as to be well tolerated; supplementation of the infant's diet in this respect, therefore becomes unnecessary. Calcium and phosphorus are added to precipitate the phytic acid present in cereals, so that an intake of these minerals sufficient for the infant's optimum needs is ensured.

M.O.F. is recommended for general use in the artificial feeding of infants of five months and over; also for infants from three months onwards where weaning has had to take place at an early age. Feeds of M.O.F. mixture may also be given to supplement breast-feeding.

commonly referred to 'venereal disease' departments; this last comprises only 17 pages, which seem inadequate when it is realized that a large proportion of the clientele of the average V.D. clinic is suffering from none of the three main venereal diseases; non-gonococcal urethritis, balanoposthitis, and *Trichomonas vaginalis* infestations are all very common, as also are warts on the genitals.

The general practitioner and the student will find this little book a mine of information. The teaching is sound and founded on personal experience, and if new methods of treatment have developed too fast for author and publisher to keep pace with them, these industrious and harassed people can hardly be blamed.

Notes on Books

Prof. GLANZMANN's brochure on epidemic poliomyelitis (*Die epidemische Kinderlähmung*. Berne: Hans Huber; Sw. fr. 6 80) contains a useful and well-presented collection of statistical data relating to Switzerland in general and Berne in particular. Since 1935 there have been three years in each of which more than 1,000 cases of the disease were notified in Switzerland: 1936 (1,269), 1937 (1,494), and 1941 (1,479). As in other countries, the disease has tended to become more widespread, the age incidence to move towards older ages, and the seasonal distribution (though a summer maximum persists) to be extended. Prof. Glanzmann is somewhat inclined to favour the view that sewage is a vehicle of infection, but the brochure—which is based upon a lecture—does not, except by providing statistical data and maps of distribution, contribute much to epidemiological knowledge.

H. K. Lewis and Co. have published at 4s. an eighth edition of Dr. R. D. LAWRENCE's booklet *The Diabetic A B C*, containing practical guidance for patients and nurses. With it is issued a third edition (price 9d.) of *The Diabetic A B C War-time Supplement*.

Preparations and Appliances

A WALKING CALLIPER SPLINT

Dr. J. MACFARLANE COWAN (Stafford) writes:

Although the design of walking calliper splints has remained unchanged for a long period, there are two disadvantages in

the customary design, and complaints by patients of discomfort are by no means infrequent. Owing to what amounts to a three-sided box construction with a non-rigid fourth side (formed by the two pins and the boot heel), lateral mobility is not well controlled. The normal arrangement of straps, or stirrups, to keep the two pins at the lower end inserted into the heel is

clumsy and not always effective, and tends to make the splints uncomfortable to wear.

It occurred to me that a four-sided box construction would increase the rigidity appreciably, and would at the same time allow of a locking device being fitted which would permit a simple and positive location of the lower end of the splint. A modification was designed and a test model constructed. This has now been worn for some months by a patient, who reports that the comfort and stability are far in excess of those achieved by any splint he has previously had.

The accompanying diagram illustrates the construction, which is not difficult and could be carried out by anyone with engineering experience. The lower ends of the splint are modified by removing the pins, and on one side fitting a piece of metal rod $1/4$ in. in diameter, and on the other side a plate with a $1/4$ in. hole and locking device as shown. The natural spring of the metal side-pieces of the splint allows it to be removed when unlocked, though in the locked position the splint is practically rigid. The simple locking device is shown in Figs. 2, 3, and 4.

I am indebted to Mr. G. M. Boon, A.R.I.B.A., for the drawing and his assistance in the construction of this modification.

A CLINICAL CAMERA-STAND

Dr. B. RICHARDSON BILLINGS (Pettis Wood, Kent) writes:

I have recently constructed a camera-stand with universal movement which facilitates clinical photography, especially photography of surgical operations under aseptic conditions. Any type of "still" or "movie" camera can be used with a lens capable of the work in hand. The head (sterilizable) incorporates hood, lamps, and reflector. Lamps are photofoods adjustable to any required position. The reflector can be either mirror or prism; in either case the same optical principle applies as in a laryngoscope, affording a "surgeon's-eye view" of the field. The mirror is removable for straight-through photography without altering other factors which should remain

fairly constant. In performance the apparatus is quick, easy, and efficient.

I am indebted to Mr. Kenneth Heritage, F.R.C.S., senior surgeon at St. John's Hospital, Lewisham, for his co-operation and for his permission to try this apparatus over his table; and to the theatre sister and staff.

BRITISH MEDICAL JOURNAL

SATURDAY AUGUST 12 1944

CONTROL OF BACILLARY DYSENTERY

Notifications of dysentery in each of the past three years have been double the average of the immediate pre-war years, and during 1944 the larger incidence has been steadily maintained. Part of this apparently increased prevalence may be due to greater awareness of the infection, together with a greater use of laboratory facilities, for clinical diagnosis of the mild endemic dysentery in this country is not easy, and the 7,000 annual notifications must represent only a small part of the total morbidity. Thus if the incidence of dysentery in a community is a measure of current hygienic standards we should have to admit that these standards have fallen in recent years. Added to that is the very real risk of more severe types of dysentery being introduced by troops returning from abroad. Indeed, Shiga-dysentery carriers have already been identified among Italian prisoners of war here. Dysentery is still one of the major epidemic infections of war, and improved cultural methods have shown that convalescent carrier rates may be as high as 80% of affected cases, so that movements of troops are likely to introduce the disease to unsalted Service and civilian populations. This hazard must be much in the mind of the Army hygienist at present, and it is proper to consider what are the most effective measures for preventing the dissemination of dysentery both at home and abroad. But first we need to know how the infection is spread.

Explosive outbreaks of dysentery are less common than happens with the enteric fevers, and epidemiological evidence suggests that case-to-case infection is the usual mode of spread in civilian communities. The infector is more likely to be the missed mild case or convalescent or healthy contact carrier than the typical clinical case, which is quickly recognized and isolated. The infecting organism may be transferred in a variety of ways, but the infected food-handler who has not been disciplined to hand-washing after using the w.c. and before handling food is particularly dangerous. Flies undoubtedly play an important part in spreading the disease in subtropical countries, where the incidence of dysentery is closely related to the seasonal prevalence of the fly. But flies flourish also in temperate climates, particularly when sanitation reverts to more primitive forms as with armies in the field, or when food-residues are salvaged and hens in the back-garden contribute to the larder. Spread of infection by contaminated water supplies is unlikely, but milk-borne outbreaks may and do occur. In these circumstances control of dysentery depends primarily on high standards of public sanitation and personal hygiene, but these are the prophylactic measures which are least easy of attainment by armies in the field or in devastated towns. The Army

has, however, aimed high in its hygienic standards by disposal of excrement to prevent fly-breeding, by close supervision of cookhouse and staff, by various anti-fly measures and by educational talks. It will no doubt be the task of the medical staff of G.S., the Allied Army's Civil Affairs branch, to do the same for liberated European towns. At home there is need for greatly increased facilities for public and private lavatories for hand-washing, a lavatory which, after use of the w.c., should be as automatic as adjusting the dress.

In dealing with an outbreak of dysentery further spread will be prevented not so much by isolation of the clinical case as by detection and cure of the missed case and convalescent and contact carriers,¹ whose numbers may far exceed the patients with clinical dysentery. Detection has been greatly facilitated by the use of desoxycholate-citrate agar and the rectal swab, but, except in "closed" communities, this is not a very practicable procedure. Cure of the clinical case of dysentery is hastened by sulphamamide therapy; even sulphanilamide² seems to be effective, but the safest drug is sulphaguanidine, under which in moderate doses rapid improvement occurs with little risk of toxic effects. However, bacteriological cure is as important as clinical cure, and has been too little studied by those with opportunities for comparing the efficiency of different sulphonamides in this respect. Sulphaguanidine will usually get rid of members of the Flexner family including the Newcastle variant, from both clinical case and carrier, but, save in early infections, it is much less effective against the Sonne bacillus,³ which is more susceptible to sulphapyridine.⁴ Additional information is needed about the efficacy of sulphadiazine, popular in America and our own sulphamezathine, which, besides being relatively non-toxic, could probably be used in much smaller dosage than sulphaguanidine—a point of some importance when large numbers have to be treated in the field. As an alternative to detection and treatment of the carrier, which in widespread outbreaks may be as impracticable as isolation of meningococcus carriers is now realized to be, chemoprophylaxis may, as has happened with the meningococcus carrier, prove to be the best method of stopping an epidemic. Thus Scott⁵ quickly controlled an outbreak of Sonne dysentery in a mental institution by giving all the inmates the remarkably small dose of 0.5 g. sulphaguanidine thrice daily until four days after the last reported case was clinically well.

There has been sharp divergence of opinion about the value of two other prophylactic measures—specific bacteriophage and vaccines. Bacteriophage has been lauded for prevention and for cure of dysentery, but it is noteworthy that its advocates usually had no adequate control series, while those who had instituted this check reported guardedly or unfavourably upon it. Large quantities of bacteriophage—apparently the standard treatment for forward troops in the German Army—were captured at El Alamein; it was found to have a high potency against the dysentery strains prevalent in North Africa at the time.

¹ *British Medical Journal*, 1944, 1, 806.² *Lancet*, 1944, 1, 784.³ *British Medical Journal*, 1943, 2, 35.⁴ *Lancet*, 1943, 2, 71.⁵ *J. Amer. med. Ass.*, 1943, 122, 588.

Boyd and Portnov,⁶ therefore decided to test its prophylactic and curative value against dysentery in controlled trials among German prisoners of war. For the prophylactic test all the inmates in one P.O.W. "cage" were given 10 c.cm. of bacteriophage by mouth before breakfast on each of three successive mornings. The sickness rates in this cage and in three similar control cages were accurately kept for four weeks before and four weeks after the course of bacteriophage. The incidence of dysentery in the "treated" group was 27.5 per 1,000 in the first four weeks and 19.5 per 1,000 in the second four weeks; the corresponding figures in the control series were 11.25 and 10.29. Thus, although there seemed to be some benefit from prophylactic phage, the difference was not apparently significant, and the incidence of infection in the treated group was still higher than in the control group over the same period. Two series of cages were chosen for the treatment test. Bacteriophage was given by mouth (15 c.cm. thrice daily for two days; three 10-c.cm. doses on the third day) to all men in one group as soon as they reported sick with diarrhoea. The control group had the standard saline treatment. Analysis of the results disclosed no effect from phage therapy either in aborting the typical clinical infection or in modifying its course, although the phage persisted in the faeces for 5 to 6 days and was detectable for short periods in both blood and urine.

Prophylaxis of dysentery by vaccines has found little favour, except, perhaps, in mental hospitals. The multiplicity of antigenic types of dysentery bacilli and the severe reactions provoked particularly by the Shiga strain have complicated the problem. However, Schütze⁷ has shown that fractions of the Shiga bacillus prepared by Morgan's method give good protection to mice injected subcutaneously at two to six weeks' intervals, a higher degree of resistance being observed with the longer interval between the two injections. The U.S. Office of War Information in a bulletin dated May 8 has also reported encouraging results in the protection of children with a mixed Flexner vaccine. Thus the control of dysentery is being tackled vigorously from many standpoints, and these "combined operations" should help to prevent this troublesome and highly infectious disease gaining a stronger foothold than it already has on both the home and battle fronts.

D.D.T.: A NEW SYNTHETIC INSECTICIDE

In peacetime insect pests are often exceedingly troublesome, but in this country they do not spread disease to any serious extent. The operations of war, however, involve sending many of our soldiers abroad to live under relatively primitive conditions, sometimes in tropical or subtropical climates. Inevitably there is a considerable danger of insect-borne diseases, some of which, like typhus, malaria, and dysentery, are very serious. Usually the principal method of preventing or controlling such epidemics is to attack the insect vector. Consequently the supplies of efficient insecticides become of vital importance in

"global" warfare. At all times, but especially in war, it is an advantage for an insecticide to be synthetic. Insecticides of vegetable origin mostly come from distant countries where space and labour for cultivation are available and where the climate is suitable. These growing areas may be overrun by the enemy (e.g., Malaya); and in any case the transport of the material takes up shipping space. In the early part of this war we suffered from the disadvantage of having no wholly synthetic substitute for the widely used plant products pyrethrum and derris. Supplies of these insecticides rapidly became scarce in spite of rigid economies. The lack of suitable synthetic compounds was not for want of searching. In a number of Government and industrial laboratories in various countries a systematic examination of compounds of possible insecticidal value had been going on for a decade. The fact that nothing very striking had been found is due to the almost infinite variety of organic compounds; many thousands of samples had been tested. Quite recently, however, it has been discovered that a comparatively simple compound has outstanding merit as an insecticide. This is 2,2-bis (parachlorophenyl) 1,1,1-trichloroethane, known as "D.D.T." from the generic name dichlor-diphenyl-trichloroethane. When pure it is a white crystalline solid with a slight, not unpleasant, odour. Practically insoluble in water, it dissolves in many organic liquids; it is non-volatile and chemically rather stable. D.D.T. was first synthesized in 1874, but its remarkable toxicity to insects remained unsuspected until 1940, when the Swiss firm Geigy A.G. took out an initial patent in Switzerland. The material came to the notice of British and American scientists almost simultaneously in 1942, and the preliminary tests soon revealed its great promise. At this time the chief demands by the Allied Services were for insecticides to use against the malaria mosquito and the typhus-carrying louse. The new compound appeared to be suitable for supplementing or entirely replacing the insecticides already employed. But from the initial laboratory tests a great deal of careful investigation was necessary before D.D.T. could be produced and used on a large scale. This research was carried out rapidly but thoroughly by entomologists, chemists, and medical men at a number of laboratories both in this country and in America. By a complete exchange of progress reports the work was carried out as a unified project without reduplication of misunderstanding.

One of the first points to be investigated was the possible danger to man. This was assessed by determinations of both acute and chronic toxicity on a variety of mammals. Although we cannot substantiate statements which have appeared in the daily press to the effect that D.D.T. is entirely harmless to man, it is quite safe in the form in which it is used. The dry powder is practically harmless unless eaten; it is not absorbed through the skin, but it may be when in solution. Precautions, therefore, should be taken by operators frequently handling solutions of the compound in kerosene or other liquids. The production of the material raised a host of problems which have since been solved. Methods of manufacture have been improved; and the various impurities in commercial samples have been isolated and examined. A pilot plant

⁶ *Trans. roy. Soc. trop. Med. Hyg.*, 1944, 37, 243.
⁷ *J. Path. Bact.*, 1943, 55, 457.

was started to produce fair quantities for large-scale trials. Finally, full-scale plants were set in operation. A great deal of experimental work went to perfect the practical application of the insecticide against various pests. For use against the body louse two methods were worked out. In one D.D.T. was employed in a diluted dust, and in the other undergarments were impregnated with it to render them louse-proof. The dust is useful for speedy application to large numbers of infested civilians to check a typhus epidemic. The remarkable effectiveness of this method was demonstrated recently in Naples. The successful quenching of the epidemic in mid-winter has received its due recognition, and we will merely emphasize that, apart from the effectiveness of the insecticide, its ease of application was the most important factor. No other delousing method could hope to approach the maximum number of 73,000 people treated on one day. Impregnation of undergarments is most suitable for soldiers or others issued with uniform clothing. It is a most effective way of keeping a large body of men louse-free for an extensive time under difficult conditions. The treatment is imperceptible on the garments and does not readily wash out. This will be the main protection for British troops in liberated Europe where typhus is endemic over large areas. For preventing malaria, D.D.T. can be made up in emulsions and sprayed over the waters where the larvae occur. But this method, though reliable, does not give protection from the adults already present. Therefore methods of spraying from the air have been devised, by which large areas can be rendered safe before planned operations are carried out. While Service requirements must take prior place at the moment, the post-war possibilities of this new weapon against malaria are enormous. It is known that the peacetime world death rate from malaria was about 2,000,000 annually, and the annual economic loss to the British Empire alone was between 50 and 60 million pounds.

Even in Britain the insecticide will have many peacetime applications. On account of its permanent nature, surfaces sprayed with strong solutions remain toxic to insects for weeks or months afterwards. This is of obvious value for checking the persistent house-fly, especially in places like hospitals, where they are all too common and indeed dangerous. Another pest which can be attacked by this method is the bed-bug. The possibility of bug-proofing a house will come as a godsend to the harassed health authorities in some districts. There are other uses too numerous to mention; but it is clear that the large quantities being manufactured for the Forces will be absorbed after the war. Veterinary practice and agriculture will benefit, but perhaps the most advantage will accrue to human hygiene.

HEALTH OF THE STUDENT

Many people are inclined to take the health of students for granted. The "very lean, And pale and leaden ey'd" student of Thomas Hood is now thought of as a robust youth spending half his time in games. Yet in some respects, from a health point of view, students are a neglected community. Unlike their contemporaries in office and workshop, they do not come under National Health Insurance, nor are they included in any general

scheme of medical examination. Some universities and colleges, like Birmingham and Sheffield, and the women's colleges at Oxford, impose an entrance medical examination or an overhaul during the first year, and others, like Leeds and Liverpool, have an examination scheme on a voluntary basis. But many colleges have no such scheme now or in prospect. In the years of student life, from 17 to 25, tuberculosis still takes first place among causes of death; the peak incidence of tuberculosis in females happens in that age period. Medical students are perhaps better provided for than students in other faculties by reason of their immediate access to hospital facilities when ill, but that is not the same thing as preventive examination and periodical overhaul. Moreover, in their clinical years they are more exposed than most students to risk of infection of one kind or another.

The British Medical Students Association, at two conferences, has paid a good deal of attention to student health, and has co-operated with three other organizations—the National Union of Students, the Scottish Union, and the British Dental Students Association—to form a committee which has in turn produced a pamphlet¹ setting forth a long-term and a short-term policy. The discussion of a long-term policy is halted by the prospect of social insurance on something like the Beveridge plan and of a national health service. Obviously it would be better to have a complete scheme for everybody than to ask for special arrangements for students. There are, however, certain things which can be done at once. The committee of these undergraduate organizations urges that every student should be examined by a medical practitioner on entering the university or during his first term, and periodically thereafter, and that for this purpose a university should appoint a whole-time medical officer. This has already been done in the University of Birmingham, where a whole-time medical officer works in close touch with the director of physical training. Matters to which the students attach special importance are the x-ray examination of the chest, eyesight examination, dental care, and the availability of immunization against diphtheria and, particularly in the case of medical students, against typhoid, smallpox, and scarlet fever. So far as treatment is concerned attention is drawn to two insurance schemes. One of these is the Oxford University Provident Association, which, for an annual fee of three guineas, arranges for a number of services and benefits in sickness up to a stated maximum. The other is a compulsory scheme for students at the University College of Wales, Aberystwyth, covering attendance and treatment. On the more preventive and environmental side it is said that some of the smaller universities are short of recreational facilities, and some colleges have no playing fields or gymnasiums at all. The committee recommends the avoidance of a narrow scholastic outlook, the cultivation of outside interests, the encouragement of summer camps and "assisted" holidays abroad, and the accent of cheerfulness in refectories, common rooms, and libraries. An odd omission from the pamphlet is any reference to students' lodgings. Few of these nowadays are as melancholy as the digs in Lant Street, Borough, which curbed even the high spirits of Bob Sawyer, but some of those to be seen in university towns are far from hygienic. There is everything to be said for providing bright, roomy, well-managed hostels.

The health education of the student is important from a wider point of view than his own well-being. The students of to-day are destined to be the educated leaders of to-morrow, and through them will come largely the dissemination of health knowledge and wholesome habits to the general community.

MEDICAL BENEVOLENCE IN WARTIME

Sir Arnold Lawson, chairman of the Royal Medical Benevolent Fund, has issued a letter to subscribers setting out the position of the Fund after nearly five years of war. He announces with pleasure that the Presidents of the three Royal Colleges and the Master of the Society of Apothecaries have consented to serve as *ex officio* members on the committee of management. In 1943 the Fund distributed in gifts and annuities the record sum of £22,702. The experience of the RMBF in war, like that of other charities, is that there are fewer new applicants, but the circumstances of those who do apply are more urgent and distressing, so that larger grants are necessary. The income from subscriptions and donations amounted to £14,374, not quite up to the level of 1938. More subscribers have signed the seven year covenant, which, with income tax at ten shillings in the pound, has the effect of doubling the subscription. Another wartime difficulty encountered is the lack of domestic help for the old and infirm beneficiaries. The Fund has considered establishing a home of its own for these people, but the idea has been deferred until after the war, when it may be made the object of a victory endowment fund. Sir Arnold Lawson appeals to medical men, especially medical officers of health, who have such opportunities of knowing members of the profession and their friends, to act as local branch secretaries.

FREEDOM TO PUBLISH

We print in this week's *Supplement* a letter from the Secretary of the British Medical Association which has been sent to the secretaries of voluntary hospitals, medical officers of health of county councils, county borough councils, and borough councils, and to the clerks of these councils. The letter brings to light once more the practice of certain authorities of imposing a censorship on the publications of medical men in their service. It certainly seems ironical that in twentieth century Britain we should have to plead for freedom to publish the written word. It is all the more remarkable when we consider that the freedom that is being asked in the Secretary's letter is the right to publish scientific articles, which are supposedly a statement and elaboration of ascertained facts. The almost casual way in which people in this country are coming to accept the surrender of freedom as something which in some mysterious way is bound up with progress is a phenomenon for which the future historian will no doubt find sufficient reason. But at a time when the medical profession is being faced with one huge restriction on the freedom to practise we should at least do all we can to preserve the freedom to speak and to write and to publish. For with these goes the freedom to think. It was only last year that we criticized in these columns the restriction imposed by the London County Council upon its medical officers, and as a result the LCC altered its standing order to the effect that medical officers could publish books and articles on "purely technical or scientific" subjects without first having to seek permission from the Chief Medical Officer. In the amended standing order the words "purely technical and scientific" replace the words "scientific or professional" which appeared in the previous order. Why this alteration? In the profession of medicine there are very many matters of interest and importance to doctors which cannot be described by the words "purely scientific and technical." Indeed, these other matters now loom unpleasantly large, and at this moment the LCC sees fit by implication to impose a censorship upon the publication by its medical officers of their views on medical politics. Is it that the LCC is afraid of criticism of its adminis-

trative machine, or is this just another example of the arbitrary abuse of authority by those in powerful positions? We would appeal to the LCC as the largest employing authority in this country to treat its medical men as responsible adults and as free men. This is a cause which medical men generally, whether employed or practising freely, should make their own, and they should bring pressure to bear at all points until these political birthrights are restored.

FATTY LIVER AND SUDDEN DEATH

A remarkable series of cases in which sudden death was associated with an advanced degree of fatty degeneration of the liver is reported by R. L. Graham.¹ A total of 11 such cases came to his notice at Baltimore during only one year. In 6 of these there was some lesion other than that in the liver which might have been responsible for death, but in 5 which are described in detail the liver was the only organ showing any significant changes post mortem. Their ages ranged from 27 to 40 years, and in each case there was a strong history or suspicion of alcoholism. In 3 there was a short period of unconsciousness before death, accompanied in 2 by seizures described as epileptic, but in the other 2 there were no such manifestations, and one death occurred during sleep. The fifth case was remarkable in that the man concerned had been called up for Army service and submitted to a prolonged medical examination on the day of his death without any abnormality being detected. The constant post-mortem finding was a large, obviously fatty liver showing microscopically so great a distension of the cells with fat globules as to compress their nuclei. The alcohol content of the liver was estimated and was in no case so high that acute alcoholism could have been the cause of death. Blood sugar estimations were made in only one case and found to be within normal limits, the author nevertheless suspects that hypoglycaemia may be a factor in this condition. The other possibility is a vitamin deficiency, such as the inadequate diet of the alcoholic is particularly liable to cause. There is some experimental support for this hypothesis, since Sebrell and Onstott² have reported that dogs on a diet deficient in riboflavin and developing a fatty liver are liable to sudden collapse and coma, which is rapidly fatal unless riboflavin is administered. This condition is apparently unrecognized, but the occurrence of such a series in a single American city suggests that it cannot be altogether uncommon, and Graham's observations should lead others to recognize and elucidate it further.

INFECTED LIVERS WANTED

The group investigating infective hepatitis for the Medical Research Council at Cambridge are anxious to obtain specimens of liver from rapidly fatal cases of acute yellow atrophy, acute or subacute necrosis occurring in patients suffering from infective hepatitis (catarrhal jaundice), or arsenotherapy jaundice. The pieces of liver should be 4 cubic inches in size, removed with aseptic precautions, and placed in a sterile container packed in ice. Specimens should be sent thus packed on passenger train to either The Jaundice Laboratory, Department of Pathology, Tennis Court Road, Cambridge, or Dr MacCallum, Wellcome Research Institute, 183, Euston Road, London, WC1, whichever can be reached most rapidly from the dispatching centre. The specimens should be marked "To Be Called For," and a telegram sent giving notice of their arrival.

TRACHOMA IN LONDON: THE END OF A CHAPTER

BY

ARNOLD SORSBY, M.D., F.R.C.S.

On May 10, 1944, the last five remaining children in the trachoma block at White Oak (L.C.C.) Hospital were discharged and the block closed down. It would be obviously fallacious to assume that trachoma no longer exists in London, but the conclusion is warranted that the affection no longer presents a problem of epidemic proportions among school-children of the metropolis—a state of affairs that prevailed within living memory.

Elsewhere (Sorsby, 1935) an account has been given of how trachoma came to be introduced during the first half of the last century among children under the care of the Poor Law authorities. The workhouses, the private contractors' schools of the type of Dotheboys Hall, the barrack schools of the multiple and conflicting Poor Law authorities of London, and the rudimentary medical and hygienic services provided by these authorities all tended to make trachoma—and other infections—endemic in Poor Law institutions. The need for effective isolation and treatment had been pressed upon the authorities by numberless ophthalmologists and physicians; it was unanimously held by oculists that the then existing state of affairs was "an arrangement for favouring the production and spread of the disease, and then keeping it in check by unceasing, laborious, and expensive medical treatment"; and the medical officer of one of these Poor Law schools bluntly testified that "hundreds of eyes admitted healthy have been attacked here, and it is useless, and would be cowardly, to attempt to deny or conceal it." In 1872 Bridges spoke of the Anerley Poor Law School as "a great ophthalmic infirmary"; Nettleship, in 1875, found that only 20% of 8,798 children at Poor Law schools examined by him had eyes free from infection; and in 1890 Sydney Stephenson was hoping for a time "when 'ophthalmia at Hanwell' will not form a standing and attractive headline for the evening papers."

That trachoma could be stamped out by effective segregation and treatment was not merely a matter of informed opinion; it had been proved by a short-lived experiment carried out for Anerley by Nettleship and his wife at a temporary isolation school in 1872, and by Stephenson in 1889 for Hanwell in an iron-built structure which the authorities of that school had been compelled to erect against their will. But the "bane of the Poor Law school" continued with it till the end. It was not until a departmental committee of the Local Government Board reported adversely in 1897 on the whole spirit and structure of the Poor Law schools that action became possible. The recommendation of this committee that there be established one or more ophthalmic and other hospital schools under the control of a central authority for the metropolis made it possible for the Metropolitan Asylums Board to proceed with the building of the necessary hospital schools. Two such institutions, with a total bed capacity of 720, were opened at White Oak Hospital on March 20, 1903, and High Wood Hospital on July 26, 1904. Three schools had been planned in 1897, but so effective were the measures adopted at Hanwell, which had served in the meantime as a central isolation school, that doubt arose whether one school would not be adequate. The temporary isolation school at Hanwell, erected in 1889, rather than the opening of White Oak Hospital, may therefore be regarded as the beginning of the solution of the trachoma problem among Poor Law children in London. The subsequent history is one of continuous decline in the incidence of trachoma as judged by the annual admissions. By 1918 High Wood had become superfluous, and was closed down as an ophthalmic school, and White Oak itself was half empty.

In 1921 children from London County Council schools began to be admitted—a radical departure not only administratively but also clinically, as non-infectious cases, such as children with phlyctenular ophthalmia, were admitted; subsequent to 1924 all chronic eye disease in L.C.C. school-children was being treated at White Oak Hospital. As for trachoma, the following figures show the steady decline in admissions:

1903	292
1904-13 yearly average	112
1914-23 "	29
1924-33 "	34
1934-43 "	13

* Excluding the years 1915-18, for which no data are available.

† Excluding the year 1924, when there were 201 admissions from an outbreak at Poplar.

The decline in the numbers admitted during the past 10 years has been steady, as can be seen from the figures of actual admissions for each of the years from 1934 to 1943 in sequence: 21, 31, 11, 28, 10, 5, 8, 5, and 7. It is worth noting that these admissions include children from outside the L.C.C. area.

That trachoma is still not infrequent in London is only too obvious by the number of adult patients seen at the eye hospitals. It is difficult to assess the total number, but each patient presents a considerable individual and social problem, and is the source of a potential epidemic. From every point of view, early and persistent treatment is essential. The lack of persistence on the part of many patients and the no less marked lack of adequate in-patient facilities for such patients at eye hospitals raise the question whether the present-day methods of dealing with trachomatous adults could not be bettered. The L.C.C. under pressure of war made provision for the admission to one of their fever hospitals of adults suffering from trachoma, but it is possible that more radical measures are required. Indicative of what can be achieved by systematized and persistent effort, experience at Glasgow may be quoted (Sorsby, 1939). Notification was made compulsory in that city in Oct., 1914, and is still in force. The number of new cases notified has shown an almost steady decline since 1915, as the following figures show:

Year	No. of New Cases	Year	No. of New Cases
1915	112	1930	25
1916	69	1931	32
1917	90	1932	24
1918	47	1933	20
1919	85	1934	17
1920	77	1935	18
1921	68	1936	12
1922	68	1937	15
1923	62	1938	15
1924	55	1939	10
1925	41	1940	7
1926	43	1941	10
1927	27	1942	10
1928	30	1943	3
1929	45		

In terms of case rate per 1,000,000 of population, the following figures illustrate the downward trend:

Year	Case Rate per 1,000,000
1919	73
1924	41
1929	39
1934	15
1939	9
1940-3 yearly average	7

Notification was supplemented from the beginning by systematic treatment in a trachoma clinic, where examination of contacts was also carried out, and by the provision of in-patient accommodation for both children and adults requiring in-patient treatment.

In London, with its excellent school medical service, trachoma in school-children is unlikely to escape observation and treatment, but there are no systematic special provisions for the pre-school child and the adult. Statutory notification of trachoma would seem to be a necessary step; not, indeed, for the purpose of obtaining statistical data—this is a subsidiary consideration in making notification of any affection compulsory—but for the creation of the machinery needed for the detection of this insidious affection, the study of the home conditions under which it may be spread, and the provision of adequate facilities for treatment. London, with its universal contacts in normal times, is especially prone to the accidental introduction of trachoma, and under suitable conditions the disease may spread rapidly, as the epidemic in Poplar in 1924 revealed. To justify action it is unnecessary to conjure up a spectre of infection spreading from a trachoma-infested Continent at the end of the war. The experience at White Oak Hospital has shown that trachoma could rapidly be eliminated from a highly infected school population—and this experience, supplemented by that obtained at Glasgow, rather than imaginary fears, amply justifies an energetic approach to the residual problem of trachoma in the adult population.

Summary

The closing of the trachoma block at White Oak Hospital, Swanley, is recorded. Trachoma may now be regarded as eliminated from the child population of London, in striking contrast to the conditions prevailing a generation ago among the poorer sections of the community.

In the light of the history of this achievement and the more recent experiences at Glasgow, where a great reduction in trachoma has followed statutory notification and the provision of adequate facilities for treatment of both adults and children, it is suggested that the elimination and prevention of trachoma in adults in London demand that the affection be made notifiable and that statutory provision be made for treatment centres.

KING EDWARD'S HOSPITAL FUND

Guy's Hospital is to be the first to benefit from the provision made by Lord Nuffield, when the Nuffield Trust for the Special Areas was established some seven years ago, that any sums which might be available (through repayment of loans, etc.) from the Trust should go to King Edward's Hospital Fund. A first instalment of £300,000 has been received by the Fund, and Lord Nuffield has asked that out of this a grant of £250,000 should be made to Guy's. This was announced by the Duke of Gloucester when he presided at the recent annual meeting of the King's Fund. In the same speech the Duke said of the Government's health service proposals:

"We wish all success to the Minister in the very difficult task before him, and we welcome the indications he has given of his desire to find an enduring solution which will be generally acceptable. We do not believe that such a solution can be found by any method which fails to preserve the freedom of the medical profession and of voluntary hospitals. While we welcome assistance from public funds, it is of the first importance that it should leave the governing bodies of voluntary hospitals and their medical staffs unfettered in their pursuit of health and healing."

Presenting the report of the Fund's Committee on Hospital Diet Sir Jack Drummond said that the catering service had, with a few notable exceptions, been the Cinderella of the hospital services. In this respect we were a generation behind the U.S.A. and Canada. Courses of lectures and demonstrations in hospital catering, to which hospitals had been invited to send representatives, had been arranged and had been a great success. Much useful information had come out of them, including a suggestion for quarterly refresher meetings, when officers in charge of catering in hospitals might meet to discuss problems. He hoped that the time was not far distant when the difficulties caused by shortage of staff and equipment would be overcome and the feeding of patients and staff would become one of the primary concerns of hospital administrators.

The report of the Radium Committee, which was presented to the meeting by Sir E. Rock Carling, recommended that in future the clinical supervision of radium work in hospitals of the King's Fund should be entrusted to the Radium Commission, which exercised these functions through the whole of Great Britain outside the Metropolitan area. The income of the King's Fund was £325,813 for 1943, and in making this announcement the treasurer said that the Fund had given a good deal of attention to the discussions on the White Paper. "Two things," he said, "stood out as necessary: (1) in the arrangements for hospital services there should be a true partnership between the municipal and voluntary hospital; and (2) voluntary hospitals should continue to receive very large voluntary income."

It may be added as a footnote to the announcement of the £250,000 for Guy's Hospital that this will enable the hospital authorities to start on the plans (which they have had for some time) not only to restore the buildings damaged by enemy action but to bring the bed accommodation up to 1,000; to provide the latest equipment of every kind for diagnosis and treatment; and to build a new college for its medical students and create a great medical teaching centre there. It is also hoped that a "Guy's" will be erected in some country area, within easy access of the parent institute, which will provide for the physical re-education and rehabilitation of patients.

MEDICAL RESEARCH IN EIRE

The report for the year 1943 of the Medical Research Council of Ireland has been issued from its office at 85, Merrion Square, Dublin. The membership of the Council remains unchanged, except that Prof. J. W. Bigger (representing the University of Dublin) resigned owing to his continued absence from Dublin and Prof. W. R. Fearon was nominated by the University to fill the vacancy. During the year the Council continued its policy of assisting scientific investigators in schemes put before it by workers interested in particular problems. Support was also given to schemes of research into public health questions of pressing importance or interest; for example, epidemic goitre in certain areas in Co. Tipperary, and the bacteriology of epidemic diarrhoea and enteritis in Dublin. At the request of the Department of Local Government and Public Health the Council advised on the establishment of a special research into the chemotherapy of tuberculosis, and a grant of £3,000 per annum was voted by the Dail for this scheme; arrangements were also made for investigating the problem of the typhoid carrier. As in past years a number of whole-time grants and grants-in-aid were made to individual workers in various branches of medical science. The report includes a summary of work done by grant-holders during 1943 and a list of their publications.

RELIEF IN EUROPE

Some idea of how UNRRA, the organization of which was outlined in these columns on July 29 (p. 166), is getting to work was given at a press conference recently. The first phase of civilian relief (provisionally estimated to last six months) will be the responsibility of the Allied Armies and the Civil Affairs Branch of the Army. Six to eight public health officers appointed by UNRRA will be attached to the Army's Civil Affairs Branch for this first or military phase and released to UNRRA afterwards. Contact is maintained with the various Allied Governments, particularly with their medical representatives, who know what the problems of relief will be, and it is hoped to appoint further public health officers for purposes of liaison. It was emphasized at the conference that the function of UNRRA is to help re-establish and strengthen a country's national and local health and medical services so that it can deal with its own problems as soon as possible. UNRRA will not force any country to take its help, but will respond to requests. Preliminary discussions have shown that large numbers of doctors and nurses will not have to be recruited; most countries have enough personnel to carry on their normal work. Medical supplies are, however, a different matter. Agreement has been reached between Great Britain and the U.S.A. on drugs and dressings required, methods of packing, labelling, etc. The basic supplies are in two forms. (1) An emergency unit containing drugs, surgical equipment, etc., to meet the requirements of 100,000 people for one month, one hospital of 200 beds with operating theatre and x-ray apparatus, and five 40-bed hospitals. These latter are tented cottage hospitals to supply the needs of remote villages. (2) A standard unit with supplies for 1,000,000 people for three months; this unit will form a pool from which actual needs in particular areas can be met.

As already announced, UNRRA has an epidemiological bureau, which will collect and distribute information, and a special division (the Displaced Persons Division) to deal with one of the most urgent problems—the return home of refugees, with all that means in the way of medical inspection, prevention of epidemics, quarantine, immunization, etc. As UNRRA has special responsibilities for the supply and distribution of food, it has its own nutrition experts, who will investigate on the spot the actual nutritional conditions of the people. Already liaison with the three Balkan missions in Cairo—Yugoslavia, Greece, and Albania—is complete. Three doctors and three senior nurses are now supervising camps and training suitable refugees in nursing, etc., and other staff are waiting to join them.

The Pedestrians' Association states that the 35 m.p.h. general speed limit for motor vehicles that became law in the United States in October, 1942, for conserving rubber has turned out to be the biggest life-saver since the introduction of motoring. According to the U.S. National Safety Council the number of persons killed was reduced to 2,000 a month in the first month of the limit, compared with 3,920 in the corresponding month of the preceding year. In 1943 the total of road deaths was 23,300 compared with 40,000 in 1941. Though the number of cars in use has greatly diminished, a considerable part of the reduction is generally attributed to the speed limit.

Correspondence

Milk for School-children

SIR.—Dr. Alison Glover's letter (July 29, p. 160) omits any reference to one important gap in the scheme. During the school holidays not only is the milk allowance reduced by one-half but it can only be obtained if the child actually consumes it on the school premises. Now the exactions on the time of mothers of young children are at present far too great for them to be able to accompany the children, as requested, to the school premises during the morning. The position is aggravated by the fact that this year not only does the summer milk ration stand at the winter level but dried milk is unobtainable and tinned milk—on "points"—is very scarce. Nor can the last two be considered adequate substitutes for fresh milk. Again, it does not seem reasonable that this holiday milk supply should be limited to elementary schools under the Board of Education. Milk rationing for the whole community has made this distinction, once reasonable, quite unfair.

On inquiry I am informed that the milk no longer consumed at the schools during the holidays is returned to the "pool." Surely a solution would be for the milk to be delivered at the homes on production of the school-child's ration book. It has, I understand, actually been urged against this that the parents might drink the children's milk! So far as my observation goes, exactly the opposite occurs; the parents give up their own milk supply for the children.

A pamphlet entitled *Better Health*, published under the auspices of the Ministry of Health, bears on the cover: "Your Child must have that Extra Milk." Yet other Departments appear to obstruct this being effected.—I am, etc.,

Cambridge.

W. LANGDON-BROWN.

Infective Hepatitis

SIR.—I was most interested in the admirable paper on infective hepatitis by Prof. Witts (June 3, p. 739). There are more points of difference between habits of British officers and British other ranks which may be of interest as regards the mode of entry of the virus of infective hepatitis into the body. The British officer is prone to drink plain water to slake his thirst, and when he drinks spirits these are often diluted with plain water—if not out of preference then at least out of necessity. On the other hand, the British other rank rarely drinks plain water; even when ill it is difficult to get him to drink plain water. He "brews" and drinks tea at all times of the day and night, and he will drink beer if he can get it.

It is believed that the liver is the site of election for the virus of infective hepatitis. Syphilis and many of the drugs used in the treatment of syphilis are hepatotoxic agents and so can lower the resistance of the liver to any substance or infecting agent which has a predilection for attacking it. Accordingly should occasion no surprise that when syphilitics under treatment do develop infective hepatitis the disease is usually severe—or rather less benign—and of longer duration than it is in non-syphilitics. That is only to be expected.

It seems to me that valiant attempts are being made to prove that syphilitics or others under similar treatment do not suffer from infective hepatitis but suffer from post-arsenical jaundice instead. Why, I cannot fathom, because in lots of cases of so-called post-arsenical jaundice the classical clinical picture of infective hepatitis is obtained. The remainder, I agree, would appear to have an afebrile onset and present themselves with anorexia, nausea, upper abdominal discomfort, and jaundice, etc., but there are numerous cases of individuals who do not suffer from syphilis and who have not been receiving arsenic or other hepatotoxic substances who give a similar history and show similar features. Such cases are diagnosed, quite rightly in my opinion, as of infective hepatitis, even though no febrile disturbance has been complained of or noted. Furthermore, as regards so-called post-arsenical jaundice, surely it is of significance that its incidence in V.D. clinics is less pronounced when separate needles and separate syringes are used for the introduction of arsenicals into the body. It would be strange were the incidence of true post-

arsenical jaundice to fluctuate in similar fashion as infective hepatitis with jaundice does in the non-syphilitic population. In addition the fact that the pathological lesions in the liver in infective hepatitis with jaundice and in so-called post-arsenical jaundice are at least similar, if not exactly the same, would appear to support the thesis that they are both one and the same disease. It is not disputed that arsenic may cause liver damage with jaundice, but I do feel that it is erroneous to regard syphilitics, under arsenical therapy, who develop jaundice, as suffering from toxic jaundice due to arsenic and not infective hepatitis.

As regards homologous serum jaundice, it is believed to be different from infective hepatitis, one reason being that the incubation period may be as long as 90 days. It results from the introduction of serum from a human source into the body. So far no one has succeeded in producing infective hepatitis with jaundice in any form of life other than the human being. The serum producing so-called homologous serum jaundice is said to contain an icterogenic agent—presumably the virus of infective hepatitis. Well, if that is so, then the serum must contain antibodies to the virus or infecting agent of infective hepatitis. Not every person having such a serum introduced into the body develops jaundice, and those that do develop so-called homologous serum jaundice may not do so for as long as 90 days. But is this prolonged incubation period not understandable, if, as would appear to happen, an antigen and appropriate antiserum are injected together into a host frequently susceptible to the effects of the antigen, which in this case, I suggest, is the virus of infective hepatitis?

The pathological lesion in the liver is said to be similar, if not exactly the same, in all three types of jaundice. Accordingly it is difficult to believe that they are all not due to the same infecting agent, as the only points of difference are in the soil in the case of syphilitics and the mode of introduction of the virus in so-called homologous serum jaundice.

As regards symptomatology, I feel that pruritus, which though rare is less rare than urticaria and which I have found only in very severely jaundiced patients, is a pre-urticarial state and is indicative of marked impairment of liver function.—I am, etc.,

Military Psychiatry

SIR.—Lieut.-Col. H. B. Craigie's article, "Two Years of Military Psychiatry in the Middle East" (*B.M.J.*, July 22, p. 105), is of much importance and merits careful consideration.

It is stated that an analysis of the admissions at one psychiatric centre during a six-months period showed that as much as 46.2% of neurosis and 37.5% of psychosis cases had had a previous breakdown, and that in addition 38% of all anxiety neurosis and 33% of all hysteria cases showed evidence of "markedly abnormal" personalities before their present breakdown, while 20% showed evidence of a "markedly psychopathic" family history, not easy to obtain under the circumstances; also an analysis of one large series of cases showed that 79% of the neurotic sick had a bad previous history.

Of the total psychotic cases 50% suffered from schizophrenia, a particularly intractable and dangerous disease, while 30% were manic-depressive, a form very liable to recurrence, and about 7% had various degrees of mental deficiency. Of 623 such neurotic and 216 psychotic cases discharged from one hospital during a period of three months, 92% of the former group and 70% of the latter were, it is stated, returned to duty, 61% and 48% respectively to full duty.

There can be little doubt that Lieut.-Col. Craigie is correct in saying that "the potentially 'infective' nature of psychiatric casualties is always a factor of considerable importance," and that "irresolute incompetent men are useless in modern warfare," but surely it is clear that the vast majority of these cases are most unstable "misfits" who should be eliminated, as Lieut.-Col. Craigie says, and who, to quote him again, "can cause difficulties and even disasters out of all proportion to their numbers, and whose presence constitutes a continued if only a potential menace to the morale of the group as a

whole"; and yet, as stated, 92% of 625 such neurotics and 70% of 216 psychotics are sent back to duty during one period of six months!—I am, etc,

Resistance of Gonococci to Chemotherapy

SIR,—Lieut.-Col. D. J. Campbell (July 8, p. 44) draws attention to the severity of gonorrhoea affecting the Army in Sicily and Italy, and makes the statement: "Since the invasion of the Latin countries gonorrhoea has proved intractable to the former accepted methods of treatment by chemotherapy." It is possible that this decrease in the number of sulpha-drug-sensitive gonococci is a phenomenon not solely confined to the Mediterranean theatre of war. In the isolated establishment in which we work naval personnel from all branches of the Service are admitted for treatment. The disease is treated early, all the men reported as soon as they noticed a urethral discharge, and adequate and accurate dosage is assured by admitting the cases to a ward reserved solely for the purpose in sick quarters.

In the accompanying two tables the fresh infections with gonorrhoea admitted during the first six months of 1942 and the first six months of 1944 are contrasted. By a coincidence the identical number—i.e., twenty-three cases—was admitted in both periods and the figures can therefore be compared directly. It will be seen that in spite of the fact that the newer sulpha drugs—sulphathiazole and sulphadiazine—were employed, treatment took half as long again. Twice as many patients needed more than one intensive course, although the drug was usually changed with each new course to find if the organism was sensitive to the different sulpha derivatives.

TABLE I

	Number of Cases Treated	Average Grammes Drug Case	% of Different Drugs Used	Average Number of Days under Treatment
Jan-June, 1942	23	32	Sulphapyridine 96 Sulphanilamide 4	13
Jan-June, 1944	23	48	Sulphapyridine 24 Sulphadiazine 27 Sulphathiazole 49	19

TABLE II

	Number of Cases Treated	More than one Intensive Course	T A B Shock	Irritation
Jan-June, 1942	23	5	1	8
Jan-June, 1944	23	10	5	12

Posterior urethral infection was present in 50% in 1944 as opposed to 35% in 1942, as evidenced by the necessity for irrigation treatment. No fewer than five cases required T A B shock as opposed to only one in the earlier series. Finally, the average number of days required for a cure (including at least two days' observation after treatment) was nineteen in 1944 and thirteen in 1942, although two of the 1942 cases were complicated by a syphilitic infection, whereas the 1944 cases were apparently straightforward. The usual adjuvant methods for investigation and treatment were used where indicated—urethroscopy, sounds, T A B shock, prostatic massage, Sitz baths, and so on. All the patients reported exposing themselves to infection within the British Isles. There were no metastatic complications.

One case included in the 1944 series is of special interest. The patient was treated over a period of sixty-eight days with 26 g. of sulphapyridine, 52 g. of sulphathiazole, and 52 g. of sulphadiazine, T A B shock on ten occasions with brisk reactions and irrigations. At the end of this period he still had a purulent discharge containing gonococci. He was therefore put on a continuous intramuscular drip of glucose saline and given 100,000 units of penicillin in twenty-four hours. A further 200,000 units were given over forty-eight hours and no gonococci have been demonstrated since then, although there has been a slight watery urethral discharge on two occasions. If sufficient penicillin becomes available in the future it would be reasonable to use it for gonococcal cases after two intensive courses of a sulpha drug have failed to effect a cure.

It would be unwise to draw conclusions from such small series of cases, but as these infections were contracted under

similar conditions it appears that gonorrhoea in this country is becoming progressively more resistant to treatment with sulpha drugs, including the newer variants.—We are, etc,

SELWYN TAYLOR.

Gonorrhoea on the Continent

SIR,—The type of gonorrhoea in males met by Lieut.-Col. D. J. Campbell in Italy (July 8, p. 44) is exactly the type which was familiar to the venereologist all over middle Europe during the pre-sulphonamide era. Simple uncomplicated gonorrhoea of the anterior urethra was rare; the infection spread rapidly to the posterior urethra, and complications as mentioned by the author were only too frequent. Correspondingly, there was a high number of complications in the female patients. It was thought that a large proportion of the complications could be explained by the early intensive local treatment generally used—namely, syringing or Janet's method in the male patient and intracervical treatment in the female. In contrast to the British treatment with potassium permanganate generally practised, protargol, albargine, and other silver-salt solutions were widely used on the Continent. As Lieut.-Col. Campbell did not subject his men to an early intensive local treatment this explanation has to be abandoned. A difference in the virulence of the gonococcus seems probable. With the advent of sulphonamide treatment the number of complications in the male and female decreased on the Continent, but did not reach such a low level as in this country.—I am, etc,

Preston

A. FESSLER.

Rheumatic Fever and the Sulphonamides

SIR,—Dr W S C Copeman's letter (July 22, p. 127) raises an interesting point. Some time ago I wrote to Cmdr. Coburn of the United States Navy as follows:

"I notice that your experiences have been similar to mine and you have found that treatment of tonsillitis with sulphonamide compounds has not decreased the liability to rheumatic fever, and yet sulphonamide administered for long periods at a time in small doses seemed to have a prophylactic effect. I am wondering if you could suggest any explanation as to how these two apparently opposed actions can be correlated."

His reply is given below:

"In answer to your question, this is our opinion. A rheumatic subject is sensitized by an acute streptococcal infection, and the administration of sulfonamide during or subsequent to infection has no beneficial effect because the trigger mechanism is already released. On the other hand, the administration of small prophylactic doses of sulfonamide checks implantation of hemolytic streptococcus and thereby prevents acute infection and the release of the trigger mechanism."

I am in agreement with Cmdr. Coburn's opinion. I would like to point out also that the administration of sulphonamides to acute rheumatic subjects does more harm than good, although I have no doubt as to its prophylactic use when given over long periods of time to rheumatic subjects in a quiescent phase.—I am, etc,

Royal Infirmary Edinburgh

SIR.—Rheumatic fever is at present regarded as a sequel, probably of an allergic nature, to an infection with streptococci—such as tonsillitis or suppurative otitis media. Treatment of an infection of this type with sulphonamides will not prevent the subsequent rheumatic reaction, and the case quoted by Dr W S C. Copeman is thus not surprising (July 22, p. 127). The great value of the sulphonamides in this field, as established in the last few years, lies in the prevention of streptococcal infections, mainly of the upper respiratory tract, in those children that have proved their special sensitivity to streptococcal infections by developing an attack of rheumatic fever. These children are very prone, as we all know, to repeated attacks of streptococcal infections only too often followed by renewed attacks of rheumatic fever with endo-, peri-, and

myo-carditis. When these children are given small doses of sulphonamides continuously from October to July, or even throughout the year, the majority of these streptococcal infections with their rheumatic sequelae can be prevented. The once-bitten heart can be spared further damage, and the lucky ones whose hearts have remained unharmed during the first attack stand a much greater chance of growing up with sound mitral and aortic valves.—I am, etc.,

London, W.1.

G. SCHROENWALD.

Bacterial Endocarditis treated by Sulphapyridine

SIR.—A case of bacterial endocarditis treated by sulphapyridine and resulting in apparent recovery occurred in my practice and would seem to be worth recording.

The patient, a youth of 16, complained of sore throat accompanied by the usual signs and symptoms of acute tonsillitis. This was treated by ordinary antipyretic drugs, and the patient was able to return to work in about two weeks. A week later I was called to see him. He complained of symptoms suggestive of influenza—pain in the back and limbs, temperature elevated, and pulse correspondingly rapid. Despite treatment the temperature remained high and his condition did not improve. I became suspicious of a slight nuchal rigidity and the presence of Kernig's sign was also suspected. He was sent to hospital for investigation. In hospital the cerebrospinal fluid was examined, but no meningococci were seen. The Widal test was also negative. A blood culture revealed the presence of a pure growth of *Staphylococcus aureus*. Changing cardiac murmurs appeared, the heart enlarged, and the abdomen became distended with ascites.

The patient was given sulphathiazole and sent home as he was not a case for a fever hospital. After his return home his condition appeared to be hopeless. I tried to obtain sulphathiazole for him, but at that time it was not available. He was therefore put on sulphapyridine and received two courses each of 0.12 g. His temperature subsided, the cardiac murmurs disappeared, and the abdominal distension gradually diminished. A short time after this he had a recurrence of the pyrexia, which rapidly subsided on the administration of a further course of sulphapyridine.

I saw him recently, two years after his illness. He complains of pectoral pain and some slight breathlessness on exertion. Examination revealed a normal-sized heart, normal in rate of beat and regular in rhythm. There was a slight roughness of the first sound at the mitral area but no definite murmur. I intend to send him for electrocardiographic investigation.—I am, etc.,

Stevenston.

R. P. LAWRIE.

Slow Induction of Anaesthesia and Vomiting

SIR.—We are all grateful, I feel sure, for the excellent advices on pentothal administration which have been tendered in your correspondence columns during recent weeks. Dr. Roberts (July 29, p. 161) in particular is to be congratulated upon his sane and lucid expositions on the subject. There is 'just one point that has been overlooked, however. Although anaesthetists are by now agreed that the administration should be cautious, both in regard to dosage and speed of injection, no one has yet mentioned the fact that slow inductions of any anaesthetic agent predispose to vomiting. Battle and air-raid casualties are unprepared for operation, and only too often have loaded stomachs which show little or no signs of emptying even after several hours' wait, this being due to the fact that digestion is to a large extent inhibited during shock, especially when morphine has been employed. Furthermore, during slow inductions the area of hypersensitivity of the vomiting centre at the lower level of the second stage (Guedel) is traversed slowly, hereby allowing a relatively long period during which the patient is predisposed to vomit. The anaesthetist is, therefore, in the horns of a dilemma; should he inject quickly in order to pass through the area of hypersensitivity in the shortest time possible or induce slowly to avoid aggravating the shocked condition? The answer lies, of course, in effecting a compromise; the first cubic centimetre may, with advantage, be given rapidly, while further administration should remain cautious.

Unless the above facts are fully realized trouble is bound to occur sooner or later. Nothing is more unpleasant and difficult than the clearing of vomitus from the pharynx of a patient with severe injuries to the face, to say nothing of the anxiety caused by watching such a patient becoming progres-

sively anoxic from a persistent laryngeal spasm! This state of affairs is not associated solely with pentothal administrations; it may occur in the course of any anaesthetic given under similar conditions.—I am, etc.,

A. H. GALLEY,
Anaesthetist, E.M.S., Sector IX.

Perineal Tears in Normal Confinements

SIR.—Before drawing the conclusion that "considerable numbers of cases with perineal tears in domiciliary maternity work are left without attention" surely one should consider the following factors.

1. (a) The district or private nurse is attending exclusively to one patient throughout the second and third stages of labour. That patient is a woman with whom the nurse has kept in touch for some months; she will also be in contact with patient and relatives for two weeks after the birth. (b) The hospital nurse may be in charge and the part charge of 2 to 6 cases in different stages of labour. She may see any one patient for a few hours only, and loses touch when the patient leaves the labour ward. Personal interest is at a minimum.

2. (a) In domiciliary work the nurse, the patient, and the relatives are pleased when the case is successfully conducted without a tear. The nurse can get home or to rest with the minimum of delay feeling she has done a good job. If a tear necessitates sending for a doctor there is a lot of additional fuss and worry in the household, and frequently a long delay before everything is "safely over." (b) In hospital work, where there is a doctor on tap, a tear is treated as part of the normal routine and very little importance is attached to it.

I consider that these factors tend to produce a smaller number of tears in normal confinements in domiciliary work, the district or private nurse being very intent on avoiding the extra inconvenience to all concerned. Also I think that hospital nurses should be taught to regard a perineal tear as a slightly disgraceful lapse on the part of the person delivering.—I am, etc.,

ISABEL M. GARDNER.

Liverpool.

SIR.—Dr. H. E. Humphrys (July 29, p. 160) draws attention to the low percentage of perineal lacerations reported by midwives. The figure 11.3% is ridiculous, even when the proportion of multiparae is high, and my figure for all degrees of laceration and episiotomy is far in excess of the 23.5% of the writer.

Midwives should be required to report all perineal and vaginal lacerations, no matter how trivial. All require repair, and the reporting of many cases should not necessarily be taken to reflect against the capabilities of the midwife. Admitting that many lacerations are inflicted by unskilful delivery it should be appreciated that a perineal laceration, which can be repaired, inflicts less permanent harm than an overstretched anterior vaginal wall, even with an intact perineum, a condition which may be associated with intractable stress incontinence of urine.

Finally, let us press for efficient perineal repair and discard the bad old practice of inserting one—or more—stitches to close a laceration involving the perineum, pelvic floor, and posterior vaginal wall. The results of the former are excellent and of the latter very poor.—I am, etc.,

Newcastle-upon-Tyne.

WM. HUNTER.

Timing in Schäfer's Method

SIR.—Misleading quotations from *R.A.M.C. Training*, 1935, made by Dr. E. F. Chapman (July 8, p. 57) resulted in criticism of this excellent first-aid manual by Mr. A. M. McMaster (July 22, p. 128). As one who has been called upon to teach first aid to medical personnel, both in this country and with the B.N.A.F., may I be permitted to quote from my own copy of *R.A.M.C. Training*, 1935, chap. 37, para. 677, and thus correct the erroneous impression which has been created: "Lean forward . . . and so produce a firm, downward pressure . . . on the loins . . . this part of the operation should occupy the time necessary to count slowly—one, two. By this means the air . . . is driven out of the patient's lungs. . . . Immediately after this swing backward, slowly releasing the pressure . . . this part of the operation should occupy the time necessary to count slowly—one, two, three."

Most standard textbooks, including the *BP* have their quota of errata, and it is possible that Dr E F Chapman's copy of *R.A.M.C. Training*, 1935, has not been revised in the light of such corrigenda or addenda. This means that, with regard to the timing of Schafer's method, uniformity in first-aid teaching does in fact exist in *R.A.M.C. Training* 1935, *First Aid in the R.N.*, and the *R.A.F. Teaching* as well as in the Royal Life-Saving Society's booklet and that of the St John *First Aid to the Injured*.

To anyone who is considering making public reference to any of the Service manuals may I therefore suggest that their nearest Service M.O. or medical orderly be approached on the subject beforehand, as the latter are responsible for keeping their manuals revised in the light of recent addenda not always available under present circumstances to civilian medical practitioners through H.M. Stationery Office. This frequent revising of all manuals is more than a duty in the Services—it is inspired by their great aim to disseminate a high standard of first-aid teaching as modified by recent advances, and thus maintain at the lowest possible level the number of war memorials—I am, etc.,

War Memorial Hospital Woolwich

SAMUEL HALES

Results of Colles's Fracture

SIR,—The interesting letters in recent issues (July 8, p 55, and July 22, p 126) on the subject of plaster of Paris in the treatment of Colles's fractures prompt me to record my own satisfactory experience of the non-plaster method. Some 16 years ago I sustained a Smith's fracture of the right wrist, and, alarmed by the results I had seen in others, I determined to concentrate on a movable joint. From the second day the splints were removed three times a day for massage and exercise. In two weeks I was able to use a knife and fork in public without even a bandage on my wrist, in four weeks I drove my car 60 miles, repeating the journey next day, with no ill effects beyond disturbed sleep for a few nights.

One point I would like to stress is my belief that the successful functional result, with some thickening of the ulnar bone as the only deformity, was in large measure due to the fact that the bones were x-rayed and set within half an hour of the accident, thanks to the kindness of my colleagues—I am, etc.,

Montrose.

PHYLIS EWART

Dangers of Lay Psychotherapy

SIR—May I be allowed through your columns to draw the attention of members of the medical profession to a practice which is being attended with increasing dangers. I refer to the rather casual way in which sufferers from neurotic disorders are taken to clinics organized and run by laymen. There are many such clinics in London and the Provinces. The directors are often well-meaning clergymen who gather around themselves a group of lay helpers. These people have had no training in psychiatry, somatic medicine, and neurology. They are incapable of making a differential diagnosis. Their equipment is a superficial knowledge of Freud and a morbid curiosity.

Recently a ministerial colleague of mine was brought to the verge of suicide through mishandling by a colony of lay psychotherapists. He had been obliged to leave his work owing to a "nervous breakdown." He went from a provincial town to London, where a well-known minister advised him to consult a lay psychotherapist. This gentleman passed my friend on to one of his helpers—a man who worked in an office and practised psychotherapy as a pastime. He proceeded to treat his patient by simple psychoanalysis. A thorough medical examination was not insisted upon, nor was a qualified psychiatrist consulted.

After a few months of this treatment my friend became mentally very ill. He returned to his home town, and immediately consulted the medical superintendent of a mental hospital, who diagnosed at once incipient manic depressive psychosis.

The gravity of the matter will be seen in the fact that his church authorities required from the lay psychotherapist a report on the minister's condition. The report stated that my friend "would not yield to treatment," and was not suited

to the ministerial life—and this after very many years of service as a parson.

It is because of such cases of ruinous mishandling that I would urge the medical profession to investigate very closely the claims and practices of lay psychotherapists. My own conviction is that no person suffering from mental disorder, however slight, should be treated by anyone who is not a recognized medical psychologist.—I am, etc.,

HORACE DOWLING

Spanish Medicine

SIR—I should like to intervene with a few considerations in the controversy on medicine in Spain. We may divide the practice of medicine into two different aspects, clinical and research work. Of the former, hardly anything can be made known abroad, and thus Spain, which is a country where the average practitioner maintains a standard at least equal to that of most other European countries, is medically underrated through her actual insufficiency in medical research work.

Yet it may be worth while to enumerate some of the Spanish contributions to medicine from the Middle Ages up to the present time, besides those of Ramon y Cajal and his histological school, already quoted in your paper. Those contributions are the following: Haemostasis through cauterization, first description of the treatment of deformities of mouth and teeth, tracheotomy, discovery of the parasite of scabies, feeding with stomach tube, discovery of ether, first use of tinctures and brandy in therapeutics; discovery of the pulmonary cycle of the circulation of blood (this a century before Harvey); treatment of malaria with bark of cinchona, operative treatment of strangulated femoral hernia, first recorded abdominal laparotomy (14th century), immunization against cholera, operative "cerclage" for kidney injuries; orthopaedic resection of kidney, first blood bank; closed plaster treatment of compound fractures, establishment of the first lunatic asylum, creation of toxicology as a science and paediatrics as a specialty, first description of such diseases as smallpox, measles, paralysis following fracture of spine, serous pericarditis, mediastinal abscess, pharyngeal paralysis, otitis media, intestinal tuberculosis, and chronic military tuberculosis.

The list is not exhaustive, and although I do not claim for my country a leading position in medicine, I think it only fair that Spain should be given her fair place among the co-builders of medical science.—I am, etc.,

Manchester

JAMES ELIAS

Treatment of Gas Gangrene

SIR,—The name of Gen. Mitchiner is itself a guarantee that his recent article (*Journal*, 1944, 2, 37) will be widely read and may have an important influence on the practice of war surgery. Therefore it is important to draw attention to two of his "thoughts" on gas gangrene: (1) that the disease has occurred less frequently and on the whole less virulently than in the last war, and (2) that antitoxin and sulphonamides seem to have next to no value if the disease is established. Because both views are so directly opposed to others that rest on well-documented evidence (MacLennan, *Lancet*, 1942, 2, 63, 94, 123, and 1944, 1, 203; Macfarlane, *B.M.J.*, 1943, 2, 636; MacLennan and Macfarlane, *B.M.J.*, 1944, 1, 683) it is to be regretted that Gen. Mitchiner has not thought it necessary to give any reasons for his vitally different conclusions. Meantime it is to be hoped that war surgeons will continue to regard gas gangrene as a dangerous and ever-present menace, and will use antitoxin and chemotherapy in the treatment of the disease. Gen. Mitchiner aims at eliminating complacency and encouraging adequate treatment. His remarks on gas gangrene are a great danger to his own objectives.—I am, etc.,

London

CLAUDE FRANKAU

H. L. Arbeiter and M. G. Levine (*Minnesota Med.*, 1943, 26, 1065) report the case of a man aged 34 who was reinfected with pneumococcus meningitis six months after the first infection. A different type of pneumococcus was present with each attack—namely, Type 25 in one and Type 10 in the other. No otitis was evident, but there was a history of a skull fracture two years before the first illness. The patient recovered both times after a combination of sulphonamide and antiserum treatment.

Obituary

L. E. SHORE, O.B.E., M.D.

Many Cambridge men will learn with regret that Dr. L. E. Shore, formerly university lecturer in physiology and Fellow of St. John's College, died in a nursing home at Bath on July 27.

Lewis Erle Shore was born at Churcham, Gloucestershire, on July 5, 1863, the second son of T. W. Shore, F.G.S., a well-known Hampshire archaeologist. He was educated first at Southampton Grammar School and Hartley College, and from St. John's College, Cambridge, where he won double first-class honours in the Natural Sciences Tripos of 1885, entered St. Bartholomew's Hospital. After graduating in medicine in 1887 he returned to Cambridge and was elected a Fellow of his College, proceeding M.D. in 1891. During the 'nineties he contributed to the *Journal of Physiology* a number of papers on peptone and on gaseous metabolism of the liver, and to these columns (jointly with W. H. Gaskell) on the physiological action and effects of chloroform. L. E. Shore was a familiar and much-liked figure in the laboratories and lecture room of the Department of Physiology at Cambridge, and with Sir Michael Foster he wrote the popular textbook *Physiology for Beginners*, which reached a second edition in 1913. For thirty years he served St. John's as junior bursar with quiet efficiency during the difficult period of recovery from a severe decline in value of the lands owned by the College. He worked on the staff of the First Eastern General Hospital, which was set up at Cambridge during the last war, and his main care was the neurological patients. At the Annual Meeting of the B.M.A. held at Cambridge in 1920 he was vice-president of the Section of Neurology and Psychiatry. His elder brother, Dr. T. W. Shore, now in retirement, is emeritus lecturer on biology at St. Bartholomew's, and was warden, and later dean, of the Medical College for very many years. His nephew, Dr. T. H. G. Shore, is physician to the Prince of Wales's Hospital, Plymouth.

Dr. FRANK BRYAN, who died on June 29 (writes L. O. L.), was born at Prestwich, near Manchester, in 1877, and educated at Clifton College, where he became a noted gymnast, winning all the belts and the Carlin Cup and representing his school twice at Aldershot. From Clifton he passed to King's College, Cambridge, where he promptly won a place in the college boat and, I understand, he was well in the running for a university blue. He took his B.A. with second-class honours in the Natural Sciences Tripos of 1898, and from Cambridge went to St. Mary's Hospital, London. After graduating in medicine he held appointments at the Middlesex County Asylum, Tooting, and at the Derby Royal Infirmary. He bought a practice at Selston, Notts, but on the outbreak of the last war he joined the R.A.M.C., and for over three years served with the rank of captain in Bombay, partly as an embarkation officer, and also in a staff appointment at the Alexandria docks. Frank Bryan was twice seriously ill, and to enable him to have a short rest he was made personal surgeon to Sir Charles Munro for a trip to Basra at the end of the war. When he returned home he became one of the original medical officers under the National Health Insurance scheme, and later went to Plymouth until he retired. From 1938 he bravely fought failing health. He was modest and unassuming, with a keen sense of humour, always cheery, and ever ready to take part in the affairs of Tavistock, where he lived.

Dr. BERNARD KELLY, who served the Royal United Hospital, Bath, very faithfully for a number of years as visiting anaesthetist, died suddenly on July 5, aged 58. He studied medicine in Dublin and took the diplomas of the Irish Royal Colleges in 1912. He was with the R.A.M.C. in Palestine during the last war, from 1916 to the beginning of 1919, mostly in casualty clearing stations. Before going to Bath he practised at Exeter and was honorary anaesthetist to the Royal Devon and Exeter Hospital. In addition to his post at the Royal United Hospital, Dr. Kelly was honorary anaesthetist to the Ear, Nose, and Throat Hospital and to the Eye Hospital at Bath. He is survived by his widow, and by a son and a daughter, who are both serving over-seas, the one as squadron leader in the R.A.F. and the other in Queen Alexandra's Imperial Nursing Service Reserve.

Dr. REES PHILLIPS, who practised for many years in Kington Road, London, S.E., died on July 16. He was b at Llanboidy, North Wales, in 1878, and from Aberystwyth College went to study medicine at the Middlesex Hospital, graduating M.B.Lond. in 1902, B.S. in 1907, and M.D. in 1913. His early appointments were those of obstetric house-physic at the Middlesex, house-surgeon to the Brighton Hospital Women, and assistant medical officer to the Lambeth Infirmary. He had been surgeon to the M Division of the Metropolitan Police, public vaccinator for the borough of Lambeth, a before the last war was M.O. to the 24th Battalion of London Territorial Regiment. During the war he served Gallipoli, Egypt, and Palestine, and reached the rank of lieutenant, R.A.M.C.(T.A.); he was mentioned in dispatches awarded the Territorial Decoration. On returning to civil life he took the D.P.H. in 1920 and the D.M.R.E. in 1921. Dr. Rees Phillips joined the B.M.A. in 1913.

We regret to announce the death on July 31, at his home Southcote Road, Reading, of Dr. HENRY JOSEPH MILLIGAN, M.C., who had been medical officer of health and school medical officer for the county borough of Reading since 1919. He took his medical course at the University of Glasgow, graduating M.B., Ch.B. in 1905, and proceeded M.D. in 1919 after taking the Cambridge D.P.H. Dr. Milligan's first appointment was that of assistant medical officer to the Southcote Hospital, under the old Metropolitan Asylums Board. He returned to Glasgow as senior assistant medical officer at the Eastern District Hospital, and next moved to Bootle to take the posts of deputy M.O.H. and tuberculosis officer. Meanwhile he had been called to the Bar as a member of Gray's Inn. During the last war he served with the R.A.M.C. and won the Military Cross, retiring with the honorary rank of major. He was a Fellow of the Society of Medical Officers of Health and acted as examiner for the Royal Sanitary Institute, of which also he was a Fellow. He published articles on infant welfare and the health of school-children and on the supervision of pasteurized milk, and was responsible for eighteen annual reports on the health of Reading. Dr. Milligan had long been a member of the B.M.A. He represented his Division at the Annual Meeting of the Association in 1923, and was a member of the Central Council from 1932 until 1938. He served on the Public Health Committee for the same period and on a number of subcommittees and *ad hoc* committees at headquarters, including the Maternity and Child Welfare Subcommittee.

The Services

Major-Gen. Sir Ernest Cowell has been awarded the American Legion of Merit for distinguished service to the Allies. He recently came from the Middle East to Northern Command as Deputy Director of Medical Services.

Majors (Temp. Lieut.-Cols.) W. J. Young, M.B.E., I.M.S., and R. B. Davis, I.A.M.C., have been awarded the D.S.O., and Capt (Temp. Major) R. K. Pilcher, Capt. F. R. Glover and H. Pozner, R.A.M.C., and W. Thomson, I.A.M.C., have been awarded the M.C. in recognition of gallant and distinguished services in Burma.

CASUALTIES IN THE SERVICES

Major LESLIE ROLAND JORDAN, who died of wounds on July 15 in Normandy, joined the R.A.M.C. in 1940 and finally was commanding officer and surgeon of a field surgical unit. He studied medicine at Bristol, graduated M.B., Ch.B. of the University in 1931, and obtained the F.R.C.S. diploma in 1934. After holding house appointments at the Bristol Royal Infirmary and Royal Hospital for Sick Women and Children he was R.M.O. at the National Temperance Hospital, London, and then settled in practice at Muswell Hill, becoming surgeon to the Hornsey Central Hospital and clinical assistant at the Central London Throat and Ear Hospital. He joined the B.M.A. immediately after qualifying.

A. H. C. writes: Capt. S. C. H. HOOD, R.A.M.C., was educated at Tonbridge School, where he had a brilliant career, both entering and leaving with exhibitions, the latter to Caius College, Cambridge. He came down from Cambridge in 1939 after only two years, forsaking a certain First in the Natural Sciences Tripos because he felt it his duty to qualify and get into the Services as soon as possible. He did his clinical studies at the Middlesex Hospital, where he collected no prizes merely because he entered for none, yet had he tried he would have done great things clinically. He must have been among the first troops to land in France, and soon earned the admiration and affection of his fellow officers and men by his bravery in battle and selfless application to the job in hand. Before his death in action he was recommended for the Military Cross.

Wounded—Temp Major D S Clark War Subs. Capt. R C Droop, T H Harrison, W R Lamb, Lieut. V O G Smith, R.A.M.C.

Killed on active service in Normandy—Capt. A Ramage, R.A.M.C.

DEATHS IN THE SERVICES

The following tribute to Surg. Rear Adm. G. I. BUCKERIDGE comes from Surg. Vice Adm. Sir Basil Hall. For a few men it is possible to gain universal popularity and affection, to be free from the enmity of others, but Guy Buckeridge achieved this by his charm of manner, courtesy, and complete freedom from affectation. His medical education was at Guy's and soon after qualifying in 1903 he joined the Royal Navy. In this Service he had a distinguished career, his first appointment, before returning under the age limit, being that of surgeon rear admiral in charge of the R.N. Hospital at Haslar. Buckeridge had a flair for administrative work, and for several years was employed in this duty at the Admiralty, where he was at one time Deputy Medical Director General. His legal type of mind, judgement and great aptitude for seeing the possible consequences and contingencies arising from any decision or proposed regulation made his opinion and advice invaluable. After retirement he held an appointment with the International Council for Non Intervention in Spain, in which his experience and character were great assets in dealing with difficulties inherent in an international organization. During the present war he acted as chair man of a Medical Examining Board at Acton. Buckeridge was an extremely well read man, and had a vast and accurate knowledge of French and English history. Possessed of a very acute sense of humour, and a quaint manner of expressing his opinions of men and matters, he was a most delightful companion. His sudden death on July 14 has created an empty space in the lives of all those who were happy to be his friends.

ROYAL COLLEGE OF PHYSICIANS OF LONDON

At a quarterly Commemoration held on July 27, with the President, Lord Moran, in the chair, the following were elected officers for the ensuing year: **Censors**, A C D Firth, George Graham, W H Wynn, Donald Hunter; **Treasurer**, C M Hinds Howell, **Registrar**, H E A Boldero, **Assistant Registrar**, A A Moncrieff.

The following awards were announced: The Gilbert Blane Gold Medal to Surg. Cmdr W A. Hopkins, R.N., and the Bisset Hawkins Medal to Brig J A Sinton for his work on preventive medicine and particularly malaria. Lord Moran was appointed representative of the College on the General Medical Council. Dr John Parkinson was appointed Harveian Orator for 1945 and Dr W Russell Brain Bradshaw Lecturer for 1945. Viscount Dawson was re-elected representative of the College on the governing body of the British Postgraduate Medical School, and Dr W G Wylie on the Child Guidance Council. Sir Edmund Spriggs will deliver the Harveian Oration on Oct 18.

The following, having satisfied the Censors' Board, were elected to the Membership of the College:

B G C Ackner, M B R A F R, N H Desai, M B H P Goldman, M B J F Goodwin, M B K Hazell, L R C P, R A F, P G Holman, M B E B Jarrett, M B Robert Moore, M B F J P O Gorman, M B, R A F R, Audrey Palmer, M B F Post, M B Ljwelyn Roberts, M D, M Roth, M B P H Sanderson, M B V K Summers, M D W F T Tatlow, M B R A M C, B E Tomlinson, M B, G Watkinson, M B D N White, M B B Wolman, M B.

Licences to practise were conferred upon the following 149 candidates (including 16 women) who had passed the Final Examination in Medicine, Surgery, and Midwifery of the Conjoint Board and have complied with the necessary by laws:

J C L Adams, M S Adams, V Altman, B E Andrews, W E Anwyl, G D Arthur, C C Bagchi, Brig M Balfour, Margaret M Ballantine, D A Barker, W R Barrett, H E Batten, T C Beard, R G Bud D, D Blake, J T Blois, Kathleen A C Bowen, Johanna E G Bracer, E H Brown, D F J Brown, C F Bunting, I J Carré, M R Chaudhuri, R E Connor, P B S Cooper, P J W Corser, W E Crocker, G David, D L Davies, P D B Davies, J M Davis, D Dencker, Stella D H De Zilwa, A R Dismore, C D Drew, R D Eak, and E W Ellis, H M Emrys Roberts, G F Ensor, D G Farquhar, M A Floyer, A C Frazer, K B Freeman, P R Fren, h T P S Frew, Joan G Garai, J Garber, Kathleen F Garstide, Barbara W Gerrard, Beryl J Goff, I H Gordon, W Gordon, A H Griffith, G J Haas, J L Hansell, P Hancé, J A Harrington, W C Harris, F H Hedges, F N Hs, J C Hingston, M D Hillel, I S Hodgson, Jones, C L Hollick, M S Hughes, M R Hunt, Brenden B Jacobs, L J R Joel, Christine M H Jones, C C Kennedy, P F Kennish, L Komar, J P Mac, Kyle, A G McEatharn, K W Leech, Leslie Levy, M J Levy, H J Lewis, A V Lillywhite, M R Liver, R G Lomax, J D Loughrey, Muriel J Lowe, J W McCona, nie P D C Mackay, I A Magnus, W Marshall, F G W Marson, J R Mayers, E T G Meade, Waldo R J Meacock, H G Middleton, S Moller, G Mon, kton, D M Montgomery, D J Morton, C P Moxon, A H R Muir, A O Nichols, J M Norman, K O M O'Meara, Faye Orm, D O'Connell, H W Palmer, G Parry, D R Patchett, B K Patel, G O Patton, I C Peebles, J T Pemberton, Nany B Penner, A J S Perfect, A Percy, Mary Ransome, J K Ratcliffe, W T D Ray, Patricia L Read, J H T Rees, L E L Ridge, P K Robinson, B S Rose, K W Ruppel, S A Sachak, A C S E Sandiford, F D Schofield, B O Scott, J C Sherris, C H Smith, P S Smith, W E Smith, J M Starks, J C Stephens, K W Symons, M Symons, Mary J L Taylor, W K Taylor, M Thomas, R H Thorpe, N Tull, G M Turner, S Wallace, P T C P Warner, P R Westall, J W Weston, E C B White, H P B Wh, J P L Wildy, T R Williams, N L Yhap.

Diplomas

DIPLOMA IN PHYSICAL MEDICINE—F S Cooksey

Diplomas in Public Health (4), Psychological Medicine (7), and Laryngology and Otology (5) were granted, jointly with the Royal College of Surgeons of England, to the candidates whose names appear in the report of the meeting of the Royal College of Surgeons of England in the *Journal* of July 29 (165) and Diplomas in Anaesthetics (34) to those whose names appear in the report of the meeting in the *Journal* of June 17 (p 830).

ROYAL COLLEGE OF SURGEONS OF ENGLAND

F.R.C.S. IN OPHTHALMOLOGY

The following letter has been sent by the President of the Royal College of Surgeons to the Council of British Ophthalmologists:

'The Council of the Royal College of Surgeons have given careful consideration to the request of the Council of British Ophthalmologists that they should grant a special diploma of Fellow of the College as a higher diploma in ophthalmology. They agree with the view that a special examination would be more suitable than the usual final examination for the Fellowship of the College for those specializing in this important branch of practice. It is also clear to the Council that the present regulations for the 'F.R.C.S. with Ophthalmology' are too exacting, in that candidates for this diploma are required first to have passed the usual final examination of the Fellowship. The Council therefore agree that there should be a special final examination for the Fellowship of the College for those specializing in ophthalmology, and that, since the standard of this examination would be comparable with that of the usual final examination, successful candidates should rank as Fellows of the College and that there should be no distinction in regard to status

Universities and Colleges

UNIVERSITY OF OXFORD

In a Congregation held on July 15 the following medical degrees were conferred:

B M B Ch—E H Brown, L M Rose, H K R Kilpatrick, L G Kitchin, F D Candler, G E L Graham, G S Jones, Mrs S N Byron, Moot. In absence: R S Wilkinson, J S Oldham, S Blackard, F O, Daunt, A R Dismore, H J L Marriott, J Roberts, V H Whetle, R R de Mowbray, P V Wadsworth.

UNIVERSITY OF LONDON

The following have passed the examinations for the Academic Postgraduate Diploma in Medical Radiology: Patricia P Franklin and David Raeside.

The following have completed the Third (M B, B S) Examination for Medical Degrees: April, 1944.

Honours—E A Fairburn (distinguished in pathology), J C Taylo (ds distinguished in applied pharmacology and therapeutics).
Pass—Gulldys V S Aldridge, R A Allen, J Alterman, E A Andrade, A A Baker, P E Balder, A P Bentley, H Bentley, H Bynsh, C C Bowley, E Brennan, J L Brennan, P R Bromage, R Cannon, M B Carson, J Cashman, P B R Clarke, T J A Clarke, M D Collins, M D Crennan, Ada I Date, Barbara S Davies, J E Davies, C E Dent, Pamela H Deakie-Clark, Mary P Douglass, D C H Draffin, D V Evans, Winfred J Ferraby, R Finney, I H Fothergill, J Fry, A J P Graham, G Grant, Audrey M Gray, J R Gray, B V I Greenish, G A Griffin, Ruth M Haslam, G Henington, A T Hunt, Los E. Hurter, Rosemary Jackson, P S Jackson, W C Johnson, June M Kingan, S M Kinsley, C H R Knowles, G de J Lee, H L Le Vau, ver, Dit Durell, M C W Long, Anne I Mackessack, Joan Martin, R Merryweather, K H Miller, P J W Monks, Stella M Murray, Catherine A Neill, J A Nissim, A J P Oldham, D B L Pailthorpe, P E S Palmer, B W T Pender, V J Penman, H A Philcox, Ella Preiskel, J H Rey, P Rib, I Charlotte Salva, E S Shalom, Angèle M P P Snow, Rachel F E H Spicer, F M G Stammers, D N Stevens, J W Stewart, I H Syed, P M Vasey, Patri, a E Q Walsh, J C P Weber, G P West, J D A Whetla, K C Willett, T J Wilmot, J L Winkler, A M Wood, N L Yhap.

U.C.H. MEDICAL SCHOOL

The following scholarships, exhibitions, and prizes have been awarded at University College Hospital Medical School:

Goldsmid Entrance Scholarship (1), J P Johnson; (2) Miss E A Bryan. **John Goldsmid Entrance Exhibition** J P Moxon. **Filster Entrance Scholarship in Pathology** W G Spector. **Atchison Scholarship** A S Smith. **Atkinson Morley Scholarship** D A W Edwards. **Magrath Scholarships** Medicine, R E Wargman; Midwifery, E A Andrade. **Erichsen Prize** and **Alexander Bruce Gold Medal** O L Wade. **Lytton Gold Medal** Miss M Farquharson. **Miss M E Hughes Fellowship Gold Medal** Miss M E Hughes. **Fellowes Silver Medal** D W H Barnes. **Wilfred Trotter Medal** Miss M E Hughes. **S G A Forsyth Tuke Browne Medal** C E Dent. **Suckling Prize in Obstetrics and Gynaecology** Miss S M Howarth and Miss P M Lloyd. **Filster Exhibition in Pathology** D A G Gahan.

UNIVERSITY OF GLASGOW

A series of meetings will be held in the Department of Ophthalmology on Wedne days from Sept 6 to 27, at 8 p.m. The meetings are open to all medical practitioners and senior students interested in ophthalmology.

or privileges between Fellows thus admitted and those admitted under the present regulations. The Council have no right under the existing Charters to make this arrangement, but they are prepared to seek powers to grant a diploma of F.R.C.S. in Ophthalmology to candidates who have passed the primary examination for the Fellowship and a special final examination on the lines submitted by the Council of British Ophthalmologists. It is anticipated that two ophthalmic surgeons would be required on the Examining Board, and it is proposed that they should be Fellows of the College and additional members of the Court of Examiners. Two other surgical members of the Examining Board would be selected from the general surgeons on the Court of Examiners and they would take part in some of the oral parts of the examination."

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

The quarterly meeting of the Council was held in the Medical Institution, Liverpool, on July 29, with the President, Mr. Eardley Holland, in the chair.

Mr. Eardley Holland was re-elected President to take office in October next, and the following officers were also elected: Vice-Presidents, Prof. William Gough and Prof. D. Dougal; Hon. Treasurer, Dr. J. P. Hedley; Hon. Secretary, Mr. G. F. Gibberd (Mr. W. Gilliatt was appointed deputy honorary secretary in the absence of Mr. Gibberd on active service); Hon. Librarian, Mr. F. Roques; Hon. Curator of Museum, Mr. A. W. Bourne.

The following were elected to Fellowship: Dr. Leonard Colebrook, Prof. Leonard G. Parsons; and the following candidates were elected to Membership: J. N. I. Emblin, J. P. Erskine, A. H. MacLennan, Agnes M. Stewart, Elsie M. Terry, Irene M. Titcomb.

Christina McD. McTaggart was admitted to the Membership *in absentia*.

Medical Notes in Parliament

Parliamentary Medical Group

The Parliamentary Medical Group have held three meetings during the week ended July 29. Among other subjects they are exploring the possibility of postgraduate facilities being made available in medical schools and universities in this country for selected Indian medical graduates after the war. At their last meeting they received representations from associations concerned with the treatment of tuberculosis, concerning the difficulties resulting from the shortage of domestic and nursing staff of institutions caring for tuberculous patients.

India's Population and Nutrition

Mr. PETHICK LAWRENCE opened on July 28 a debate on India. He said that if the population of India increased at the present rate famine might recur. Col. ELLIOT said that in the East it took four families on the land to feed one family in the town. In the West one family on the land fed four families in the town. India raised only enough food to keep half her population alive after the age of 22, yet her population was going up at the rate of 1,000,000 every two months.

Prof. A. V. HILL said that in India food was two-thirds of what would be necessary for a decent standard of life. Disease and malnutrition so worked together that any internal strife and disorder, or any epidemic like that of 1918, might produce a major catastrophe. If health measures improved and food production and distribution were bettered, the increase would become 7,000,000 or 9,000,000 per annum. How could food supplies catch up with so riotous an urge to reproduce? That problem required complete co-operation all round, with hard thinking and hard work. Sir STANLEY REED said the growth of the Indian population was now out of control. There had been famine in 1891; famine in 1899 with plague; later the great influenza epidemic. In the following 20 years there were none of these disturbances. Good administration swept away the forces which had kept the population within reasonable proportions.

Mr. AMERY said the causes of the Bengal famine and of the epidemics which followed were to be investigated by a Commission with Sir John Woodhead as chairman and with Dr. Aykroyd, Director of India's Nutritional Research Laboratory, among its members. This investigation would cover the problem of famine and its prevention all over India. In Bengal last year 700,000 human beings died directly from starvation or from endemic diseases which broke out on a large scale where there was malnutrition. The Health Survey Development Committee under Sir Joseph Bhore was studying

public health, nutrition, maternity and child welfare, housing, water supply, and malaria and other endemic diseases. It was expected to report this year.

Riboflavin Content of Beer

On Aug. 2 Mr. KEELING asked the Lord President of Council the grounds on which the Advisory Committee Alcohol, appointed at his request by the Medical Research Council, decided that alcoholic beverages were not significant sources of any of the known vitamins, in view of the statement in Nutrition Bulletin No. 8 that the rarity of symptoms of deficiency in the British people was partly attributable to the presence of riboflavin, vitamin B₂, in beer. Mr. ATHERTON replied that the committee originally appointed by the Control Board (Liquor Traffic), and later reconstituted by Medical Research Council at the request of the Home Office produced the book *Alcohol: Its Action on the Human Organism* many years before knowledge of riboflavin was available. Information on the point mentioned was not available ever since 1938, when the latest edition of the book was published. Recent publications indicated that riboflavin was present in beers, but it was clearly impossible to say with assurance what extent the rarity of symptoms of deficiency in the British people was in fact due to beer drinking, particularly since there was no evidence of a general deficiency of this vitamin in non-beer-drinkers.

Pneumoconiosis: Preventive Measures

On Aug. 1 Mr. J. GRIFFITHS asked the Minister of Fuel and Power whether, having regard to the considerable increase in the numbers of men who were being certified as disabled from pneumoconiosis, he would make a statement of the steps now being taken to prevent this disease, and at how many collieries effective preventive measures had been adopted. Major LEO GEORGE circulated the following reply: In the coal faces the most effective measure so far developed is usually the application of water—in quantity which, to avoid other dangers, must be carefully controlled—either by infusion under pressure through boreholes into the coal before it is worked, or by "wet cutting," in which a jet of water is directed on to the pick as the coal-cutting machine works along the face. These two methods have been developed and applied in South Wales. Special arrangements have been made to ensure that the collieries on a high priority basis the large quantities of water piped required. In hard-heading work the older methods of wet drilling or collecting the dust produced by dry-drilling continue to be employed, and mist sprays are used to suppress dust caused by blasting.

Food Supplies in Greece

On Aug. 1 Mr. HARVEY asked the Parliamentary Secretary to the Ministry of Economic Warfare whether he would give the latest available information on the position of the civilian population in Greece in regard to food supply and the measures being taken to relieve grave malnutrition. Mr. FOOR replied: The harvest has just been gathered, so there has been a recent improvement. Nevertheless, it would be misleading to generalize about the food situation in Greece as a whole, since conditions vary widely between the larger cities, the provinces, especially those areas where there is active guerrilla warfare, and the islands. In those areas which are the scene of active conflict, food supplies remain a very serious problem. In certain districts conditions have been aggravated by the action of the German authorities in destroying or seizing native produce. Moreover, military operations and the requisitioning of lorries involve considerable interference with transport and distribution. Conditions of acute shortage continue among a large part of the island population, owing to the great difficulty of sending supplies. The House is already aware that relief foodstuffs are being shipped to Greece at the rate of approximately 32,000 tons a month. In addition, arrangements have recently been made for supplies to be sent in Turkish coastal vessels to Mitylene and Chios, and the first cargo has been delivered.

Notes in Brief

The Royal Assent was given on July 27 to the Food and Drugs (Milk and Dairies) Act.

Between July 1, 1943, and June 30, 1944, 4,762 applications were received by the Medical Board under the Coal Mining Industry (Pneumoconiosis) Scheme. Of these, 1,328 were certified and 1,163 were refused certificates. The number still undecided by the Medical Board on June 30 was 2,235.

No surplus olive oil is available from Italy. There is enough olive oil in the United Kingdom to meet requirements under medical certificates, but no more.

No. 29

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended July 22.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included) (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London), (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1944					1943 (Corresponding Week)

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In England and Wales during the week the incidence of most infectious diseases fell; whooping-cough returns were 166 fewer than last week, measles 135, acute pneumonia 63, and diphtheria 20. There were 67 more cases of scarlet fever than last week, and 13 more of typhoid.

The small increase in scarlet fever was general throughout the country. The incidence of whooping-cough fell particularly in Kent, Yorks West Riding, and London, where respectively 61, 45, and 42 fewer cases were reported. Increases of 48 and 23 were recorded in Carmarthenshire and Glamorganshire. The decline in measles notifications was most pronounced in the south, Kent reporting 70 fewer cases than last week, Wiltshire 57, Middlesex 44, and London 40. Durham had 82 more cases than last week, and Southampton 86; in Portsmouth C.B. the cases rose from 21 to 88.

Two fresh outbreaks of dysentery were reported during the week: Wiltshire, Amesbury R.D. 15, and Dorset, Wareham and Purbeck R.D. 25. The only other large return was Surrey 15 (Epsom and Ewell M.B. 9). The totals for London and Lancashire were the very low figures of 7 and 6 respectively.

Twenty-one cases of typhoid were notified, the largest weekly total since January, 1942. The cases were distributed throughout eleven counties; the largest return was that of Cambridge, M.B. 5.

In Scotland there was an increase of 43 in the incidence of diphtheria, and of 23 in that of dysentery. The greatest local rise in diphtheria was in the City of Glasgow, from 22 to 48. The rise in dysentery was due to an increase in existing outbreaks; the chief centres of infection were Glasgow 25, Edinburgh 18, Lanark County 22.

In Eire a case of typhus was reported from Galway, Oughterard R.D.

Week Ending July 29

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,530, whooping-cough 2,151, diphtheria 461, measles 2,352, acute pneumonia 450, dysentery 149, paratyphoid 11, typhoid 18.

Medical News

A sessional meeting of the Royal Sanitary Institute will be held at the County School, adjoining the Town Hall, High Road, Tottenham, on Friday, Aug. 18, at 3 p.m. The programme consists of notes by the Borough Engineer and Surveyor, Medical Officer of Health, and Chief Sanitary Inspector, on (1) the replanning of Tottenham, (2) the health services in a replanning scheme, and (3) reconstruction and maintenance of houses as an immediate post-war problem. A Town Planning Exhibition will be on view in the Town Hall before the meeting.

The Ministry of Food announces that the monthly allowance of dried bananas made to approved cases of coeliac disease has been reduced from 14 lb to 7 lb. In the light of experience the Ministry's medical advisers consider this quantity of dried bananas is adequate. Applications for the allowance supported by a detailed medical certificate should be made to the local Food Office.

The Minister of Health has sent the following message to hospital staffs: "I have been much impressed during the past few weeks by the smooth efficiency with which the hospitals and casualty services of the Emergency Scheme have carried out their duties. These have included the reception, transport, and treatment of casualties arriving in this country from the battle area in Western Europe and of civilians injured by the flying bombs, in addition to the casualties arriving from other theatres of war and the various other categories of patients for whom the Emergency Medical Services are responsible. This reflects the utmost credit on the medical, nursing, and other staffs, and also on the administrative officers. Many of them have carried out their duties as mobile surgical teams and reinforcements under difficult circumstances, while others have shouldered heavy extra burdens in order that these reinforcements might be released for service where they were most required. The country owes a deep debt of gratitude to all members of hospital staffs for contributing so much in this and other ways to the success of the Emergency Hospital Scheme during this important phase of the war. The signal service they have given and the public spirit they have shown, often under conditions of difficulty, are especially gratifying to me as Minister of Health. I am most grateful to all concerned."

Major-Gen. W. H. Ogilvie has been appointed a director of the Clerical, Medical and General Life Assurance Society to fill the vacancy caused by the death of Sir Cuthbert Wallace.

Diabetics living in safer areas are asked by the Ministry of Health to offer billets to diabetic children and other fellow-sufferers eligible for evacuation from London and Southern England areas exposed to flying bomb attacks. As their lives depend upon a regulated diet and daily insulin injections, it is not possible without grave risk to include diabetic children or adults in officially organized parties. Householders with experience of diabetic cases who would accommodate and look after a diabetic child alone or with its mother are asked to send their offer to the Diabetic Association, 9, Manchester Square, London, W.1. Similar accommodation is needed for elderly and infirm diabetics who have lost their homes through bombing. Persons offering accommodation are asked to state the age and sex of those they are willing to receive. Others members of the evacuation priority classes who, because of their diabetic condition, cannot find accommodation with relatives or friends should notify either the hospital or clinic they attend or the Diabetic Association.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London*. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London*. MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent, London*.

ANY QUESTIONS?

Elephantiasis after Plaster

Q.—A woman of 40 has elephantiasis of one leg due to application of plaster-of-Paris for 14 weeks some three years ago. Her renal function tests are satisfactory. What form of treatment will improve this complaint?

A.—It is probable that this condition could have been prevented if elastic compression had been applied to the limb as soon as the plaster was removed—starting 3 years late is a severe handicap. An attempt should be made, however, to get rid of as much of the swelling as will subside after rest in bed for a few days with the leg elevated, and then an Unna's (zinc gelatin) paste bandage should be applied from the webs of the toes to the upper limit of oedema. This or a similar supporting bandage should be worn continuously till the leg no longer swells beneath it—that is, till active muscular movement has restored the circulation—a process which may take some months to complete.

Repairing Torn Perineum

Q.—Will you please describe the U.C.H. method of "repairing the perineum" at childbirth?

A.—The perineum is not repaired until after the birth of the placenta except in cases of operative delivery, when repair is carried out as soon as the child is delivered and while the patient is still under the anaesthetic. In all other cases local analgesia is used. The patient is placed in the lithotomy position, and a syringe, preferably of 20 c.cm. capacity, is charged with a solution containing 1/2% procaine and 1:200,000 adrenaline. Commencing posteriorly, this solution is injected under the margins of the tear at both sides through the whole of its length, extending up the vaginal wall as far as necessary. A swab moistened in this solution is placed on the raw surface and an interval of five minutes is allowed for the analgesic to take effect. A self-retaining retractor is now inserted (Gelpi's pattern is useful) so as to give a good exposure of the posterior vaginal wall. The vaginal mucosa is now united with interrupted catgut sutures down to and including the mucocutaneous junction. The retractor is now removed, and two or three deep catgut sutures are inserted into the muscles of the perineum. The perineal skin is now united with interrupted silkworm-gut or nylon sutures. These are inserted so as to take in the superficial part of the muscle layer. It is important to leave no dead space. These sutures are loosely tied, to allow for the oedema which is likely to occur; the ends are left long and knotted together. To complete this small operation, a rectal examination is made to ensure that there has been no damage to the rectum and that no sutures have been inserted through the rectal mucosa. A further important point in extensive tears is that, before repairing the perineal muscles, it is essential to look for damage to the external sphincter ani. This is

often torn, usually to one side of the midline. The ends should be found and brought together with one or two mattress sutures of catgut. All perineal tears that exceed half an inch in length should be sutured. It is impossible to repair such tears adequately with one stitch. When the perineum is torn for a distance of half an inch or more the vaginal wall is almost always torn for an equivalent, or even greater, distance. This must be exposed and properly sutured.

Treatment of Whooping-cough Paroxysms

Q.—Is ether of value in severe paroxysms of whooping-cough apart from convulsions? What are the recommended doses for the intramuscular and rectal routes at 1 month and 1 year? Which route is considered the best? Is there any danger of sloughing by the intramuscular route?

A.—There is no evidence to prove that ether is of any value in controlling the paroxysms of whooping-cough, and its use has been abandoned in fever hospitals. The intramuscular route is painful and occasionally gives rise to abscess formation; 0.5 to 1 ml. every second day are suitable doses at 1 month and 1 year respectively. Rectal injections of 10% ether in olive oil in doses of 10 to 30 ml. twice a day are safer. Luminal, 1/12 gr. and 1/4 gr. respectively twice a day, is a much more effective remedy, and free from risk provided cumulative effects are watched for and avoided.

Shock Treatment

Q.—Has insulin injection in small amounts been used and found effective in the mild depression phase of mild psychosis?

A.—This treatment is of no use in this condition except to improve nutrition and for its suggestive effect. If the diagnosis is correct, then electrical convulsion therapy would be effective in such a case. On the other hand, if the condition is mild, it may clear up very soon anyhow.

Tug-of-War for Girls

Q.—At a grammar-school sports day I asked why the senior girls should not have a tug-of-war. The teachers were horrified. They said, "It wouldn't be safe for girls." I had no proper evidence to answer this objection, and could only say that girls were to-day doing work as railway porters, farm labourers, heavy lorry drivers, and heavy load lifters, all without any apparent harm. I should like to know what is the opinion of those fit to judge.

A.—As girls have seldom engaged in these, there is no direct evidence that tugs-of-war would be harmful to them. As a physician who was once an athlete, I regard the objection to this form of exercise for girls as reasonable. Having taken part in many tugs-of-war I regard them as being, from the medical standpoint, the least desirable form of athletics commonly undertaken by adolescent boys. The comparatively long periods of stasis with contracted muscles and fixed thorax and the absence of rhythmic movement suggest that the cardiac strain involved is probably greater than in more mobile exercises. The female muscles, seen at their best in more graceful athletics such as the back crawl in swimming, would, I think, be less adapted to tug-of-war. I should unhesitatingly support the teachers' objection on medical as well as aesthetic grounds. Tug-of-war is certainly the least graceful of all sports.

Chronic Vasomotor Rhinitis

Q.—What is the approved treatment for chronic vasomotor rhinitis with obstinate nasal obstruction, especially at night? Relief with ephedrine or benzedrine is only temporary.

A.—The usual treatment for this condition is to cauterize the inferior turbinates under a local anaesthetic. A deep linear burn is made from behind forwards, along the medial aspect of the bone. This results in a scar, which binds the spongy tissues down to the bone. If the posterior ends of the turbinates are much enlarged, they should be removed by snare under general anaesthesia.

Cause and Treatment of Urticaria

Q.—What is the modern treatment, local and general, for severe and intractable cases of urticaria in adults?

A.—The treatment of urticaria is: (a) To inject subcutaneously 5 minims of adrenaline chloride solution (1:1000), and if the case is a severe one to repeat the injection of another 3 minims 1/4, 1/2, 1, 2, 4, and 8 hours later, as there will be a tendency for the symptoms to reappear when the temporary effect of the adrenaline has worn off. The adrenaline action may be sustained by injecting slow off. The adrenaline action may be sustained by injecting slow off. The adrenaline action may be sustained by injecting slow off. (b) To give ephedrine hydrochloride 1/2 gr. 4-hourly (glycerin base). (c) To relieve local irritation by warm morning and evening baths, dusting the skin with an orris-root-free talcum powder containing 1/2% menthol, or employing a calamine lotion or cream containing menthol 1% and phenol 1%. (d) To clear the gastrointestinal tract by giving an emetic early, or saline aperients, castor

oil, or calomel later (e) To reduce the food intake, forbid alcohol, and force fluids

To prevent recurrences the cause should be determined, and a careful history, the use of skin tests, and the employment of eliminative measures in the environment and diet are essential. Certain substances may cause urticaria in any individual—the injection of certain drugs (histamine, morphine, and derivatives), the eating of decomposed foods, the bites and stings of certain insects and jelly-fish, but such attacks are probably only occasional and the cause can be readily recognized.

Intractable urticaria is usually an allergic manifestation in an allergic subject. The allergic causes include (a) inhaled substances (feathers, down, animal hairs, pollens, house or occupational dusts, insecticides, moulds, and fungi), (b) ingested substances, ordinary foods or common drugs (aspirin, quinine, phenolphthalein, sulphonamides), (c) injected substances, such as an overdose of allergen following serums, blood transfusions, the bites and stings of insects, or following injected drugs, vaccines, endocrine substances, or gland extracts, (d) infectant substances from bacteria, intestinal parasites, or mycotic infections; (e) contactant substances—the touch or lick of various animals, or the use of their products in clothing or furnishings, the handling of certain foods (flour, fish) or plants (primula), the use of cosmetics, dyed clothes, or even adhesive plaster, (f) physical agents such as light, heat, cold, and trauma.

In chronic cases the first thing to do is to stop all previous medication, as drugs play such a large part in its causation. Inhalant factors are the next commonest cause, especially when cases are worse in bed, during the night, or on waking, due to a sensitivity to feathers, down, or horsehair in the bedding. During the day house and occupational dusts play an important part, and desensitization is necessary. Foods are the least commonest specific cause, but most patients suffer from flatulent indigestion, and 20 minims of ac hydrexchlor dil BP in a wineglassful of water at the beginning of each meal is helpful. The raising of the basal metabolism by adequate doses of thyroid extract is often necessary. If the cause cannot be determined or removed, the withdrawal of 10 ccm of blood from the vein at the elbow and its injection intramuscularly into the buttock on six occasions at intervals of five days is usually more efficacious than other methods of treatment recommended, such as vaccines, histaminase, peptone, calcium, or milk or wholesale surgery, the sequential removal of teeth, tonsils, appendix, gall-bladder, or tubes.

Urticarial outbursts often follow emotional storms, anger or fright, in states of fatigue, or after exertion. Such incidents utilize any available protective adrenaline and so render the sufferer more susceptible to some offending allergen acting during this adrenaline-depletion or exhaustion state.

Trophic Ulcers

Q.—I should be grateful for suggestions as to the treatment of painful trophic ulcers of the legs in a lady of 70 with very long-standing Raynaud's disease.

A.—The question does not give sufficient information about the situation and character of the ulcers. At the age of 70 arteriosclerosis can be assumed to be present and operations on the sympathetic nervous system are not advisable. Prolonged recumbency is also contraindicated by the age, and ambulant treatment with some form of occlusive dressing such as elastoplast would be preferable.

Shooting Pains in the Head

Q.—A patient aged 65 has for the last three months had a shooting pain in the right side of his head if he sneezes, strains, or stoops. Clinical examination is negative, BP 114/60. The pain lasts about 5 minutes and is never there unless started by a strain or sneeze. What might be the cause of this, and what treatment can be suggested?

A.—There is really too little evidence in this case upon which to establish a diagnosis. The most common cause is raised intracranial pressure, such as may be associated with a cerebral tumour. Tumours in the neighbourhood of Meckel's cave might cause such pain as is described, but they are usually accompanied by sensory loss in the corresponding trigeminal area. A lumbar puncture and examination of the CSF might give a pointer to the diagnosis. Until this is established, treatment should be by simple analgesics.

Exposure to Blast

Q.—What should be done if one is about to be exposed to bomb blast? Should one open one's mouth or close it, hold one's breath or breathe easily? Close the ears and nose with the fingers and close the mouth? Or what should one do to diminish the probability of concussion to the lungs?

A.—Open or Closed Mouth.—Blast does not affect the lungs by way of the mouth. On the other hand it may, at high pressures, affect the nasal mucosa and possibly the pharyngeal. On general principles, therefore, but not because of the lungs, keep the mouth

shut. At the beginning of the war there was a widespread belief that one ought to bite on something during an air raid. I could never find the basis for this belief, and its most reasonable basis appears to be to prevent people from biting their tongue when they "jump" at the explosion. I can see no use in the practice.

Hold One's Breath or Breathe Easily.—There is no empirical answer to this question, for we have not been able, in experiment, to disentangle the concussion effects on the inflated and deflated lungs. The general theory deriving from experiments suggests, however, that an "airless" lung would be less affected than one inflated. Since this is impossible to achieve, "Don't bother".

Close the Ears with One's Fingers.—Yes, definitely. Close the Nose.—In spite of the knowledge we have that at high pressures the nasal mucosa can be hurt, I should say no. Keeping the ears, mouth, and nose shut would seem to me a slightly difficult manoeuvre.

In general the best advice therefore would be to lie flat on one's belly, behind, if possible, some stout cover, even in the gutter up against a pavement—with one's mouth shut and one's fingers in the ears. Indoors keep away from glass, and take what cover one can to prevent being hit by flying debris or of being buried under debris—e.g., get into a Morrison shelter if available, or under the stairs, etc. The real danger of flying bombs is not the direct effects of blast on the chest, but the danger of being hit by bits and pieces thrown about by the blast. The direct effects are not likely to be experienced, or to be serious, except very close to the burst, where precautions of the kind referred to are unlikely to help anyway.

Transmission of Cancer by Transfusion

Q.—Is it possible for cancer to be transferred from one person to another by means of a blood transfusion? If it is possible for malignant cells to be carried in the blood stream from one part of the body to another, I cannot see why they should not be transferred from one person to another unless the blood were stored long enough to render the malignant cells non-viable. Are there any recorded cases of this occurring, and is there any evidence as to how long malignant cells would survive under normal storage conditions?

A.—Malignant cells are carried in the blood stream from one part of the body to another, but it is probable that only a proportion of such cells survive and form new metastases. If such cells were present in transfused blood the chances of survival of the cells in another heterozygous person would be so small as to be negligible. There are no recorded cases of transference of cancer by blood transfusion. Malignant cells would probably survive 2 to 3 days under normal storage conditions. Hence the reply to the lay questioner would be: In view of (a) the well known difficulty of transplanting cancer successfully from one human being to another, even when masses of living cancer cells are grafted, (b) the probable lack of viability of a proportion of circulating cancer cells even within the body of the cancer patient himself, (c) the much greater lack of viability of cancer cells in another heterozygous human host, (d) the rarity of blood from a cancer patient being used for transfusion because (e) escape of cancer cells into the blood stream is a phenomenon associated with advanced cancer, it is justifiable to answer "No".

INCOME TAX

Deductions under "Pay as you Earn": Cost of Assistant's Rooms

A S employs an assistant "at a salary of twelve guineas a week, all found." Each month the assistant receives two cheques, one for salary and one for payment of rooms. Should tax be deducted from the latter payment?

* Yes. Both cheques are in respect of emoluments falling within the class to which "pay as you earn" is applied, and the assistant is liable to tax on the full twelve guineas.

Amount of Tax Payable

W D inquires what tax is payable monthly on a salary of £525 by a single man paying £8 18s 4d life assurance premium a year.

* The calculation for 1944-5 is as follows:

Earnings		£525	0	0
Deduct Personal Allowance		£80	0	0
Earned Income		£525	10	0
		£132	10	0
Taxable Income		£392	10	0
Tax at 6s 6d on £165	0	0		
10s. 0d	£227	10	0	
	£392	10	0	
		£53	12	6
		£113	15	0
		£167	7	6
Less Life Assurance Relief £8 18s. 4d at 7s 6d.				
		£11	2	
Net tax payable for the year		£165	16	4

The monthly deduction should therefore approximate to 1/12th of £165 16s 4d—i.e., £13 16s.

"Pay as you Earn"

A. P. is employed by two authorities, one of which usually pays the fees two or three months after they are earned. In consequence some fees earned before April 5, 1944 (and therefore part of the income already assessed for 1943-4) were paid after that date and suffered deduction of tax under "pay as you earn." What is his remedy?

It has to be borne in mind that "pay as you earn" is a system of collection of tax; the old assessment procedure still operates, though on the basis of the current year instead of the preceding year. The tax payable by A. P. for 1943-4 has been reduced by 7/12ths "cancellation," but the precise amount to be cancelled is governed by special rules and apparently has not yet been calculated; further cancellation is subject to certain conditions compliance with which may remain uncertain until Nov. 5. But sooner or later A. P. will receive a statement from the inspector of taxes setting out the full facts, and he can safely wait for that statement to be sent to him. It may perhaps be added that unless the authority in question expedites its dates of payment he will not suffer deduction of tax in 1944-5 on more than a year's fees.

J. L. W. retired in 1937. During 1942-3 he received fees amounting to about £500 for examining patients. He inquires (1) whether he comes under the P.A.Y.E. system and (2) whether he is entitled to travelling expenses.

(1) The first point to decide is whether J. L. W. is assessable under Schedule E—i.e., whether he is in "employment." The answer to that depends on whether the arrangement or contract under which he works establishes the relationship of "master and servant." If it does, he is assessable under Schedule E and his earnings come under P.A.Y.E.; if J. L. W. is his own master the fees are assessable under Schedule D and P.A.Y.E. does not apply. *Prima facie* the former is the case. (2) The expense of travelling from one's residence to the place of employment is not deductible. But an exception has been made to meet wartime changes of residence, etc., subject to a maximum deduction of £10.

Sale of Practice: Expenses

N. P. has sold his practice and stored his furniture until he sets up practice again. Is any part of the expense of removal and storage of the furniture allowable?

No; such expenses are not incurred in carrying on the profession, but after the professional activity has ceased.

LETTERS, NOTES, ETC.**An Argentine looks at British Plastic Surgery**

To see ourselves as others see us is always an interesting—if at times a mortifying—experience. In a paper from the Instituto de Clínica Quirúrgica, the leading surgical clinic in South America, an Argentine surgeon describes from personal observation the treatment of fractures of the middle third of the face in British civil and military practice (*Diá. méd.*, 1944, 16, 361). The author, Dr. R. Castro O'Connor, recently completed a study of plastic surgery in this country as a British Council scholar, and his careful and detailed survey of a particular aspect of this subject would seem to indicate that he employed his time to very good purpose. For convenience, he "divides" the face into upper, middle, and lower thirds. The middle third includes the superior maxilla and the nasal, ethmoid, and nasal bones. The mode of production, diagnosis, and treatment of fractures of this region are reviewed at considerable length, and different techniques used by individual British plastic surgeons are described. The author stresses particularly the importance of the closest collaboration between the plastic and the dental surgeon, and concludes with a very generous tribute to the "inimitable" Sir Harold Gillies, with whom he spent most of his time, and also to Prof. T. P. Kilner, Mr. A. H. McIndoe, and Mr. R. Mowlem, whose units he visited for varying periods. Anglo-Argentine relations are complex and fraught with difficulties at the present time, but it is good that medical science and practice should provide common ground for countries which are not closely linked at the political level. Whatever ideological or political divisions may embarrass or disturb international relationships, medical men of all countries are animated by the same fundamental aims and interests, and are heirs to a common tradition which is as old as civilization. In an age of competing millenarian solutions to human ills, it is well that medical men should remember this and jealously guard their right to the free exchange of views and experience with professional brethren not only of their own but of other nations.

Sickness Records of Hospital Nurses

Dr. W. NORMAN TAYLOR (Radstock) writes: Dr. Wilkie (May 13, p. 670) quotes figures to show that the health of non-resident hospital nurses is not so good as that of the resident ones, and uses these figures as an argument against the system of allowing nurses to live

out. He apparently does not realize that his figures could equally well be used by an advocate for this non-resident system. They merely show that resident nurses do not consult a doctor so often, not that they are less often sick—two very different things. In other words, they could as well be used to suggest that Dr. Wilkie's nurses are being discouraged from reporting sick when living under the eye of authority. Such a state of affairs is all too common in some of our hospitals. Surely our nurses can have the same privileges as the rest of the general population, and one of those is the privilege of going sick when one feels like it—and without asking permission.

Army Council and Wounded Medical Officers

Dr. F. C. DURBIN writes: It is now the policy of the Army Council to retain in the Service a medical officer who has been so severely wounded in action as to necessitate amputation of a leg, although the individual concerned may express a desire to be released in order to join the E.M.S. By becoming a civilian he would be enabled to acquire experience in hospital practice, while if retained in the Army he is liable to be posted as medical officer to a combatant unit in this country only. There, if he does not actually stagnate, he will fail to increase his knowledge of medicine to the maximum advantage. I feel that such individuals should be given the best possible opportunities for starting afresh, particularly as most have joined up soon after qualification. Their places could easily be filled by some of the many hundreds of young men still in the E.M.S. who have been so employed since the beginning of the war. I consider it a shameful policy to utilize a disabled man in the Services against his wish. It would seem that the Army is determined to extract more than its pound of flesh.

The D.P.M.: A Minimum Requirement

D. F.-R. (Lancs) writes: I refer to your correspondent's observations upon the above (July 15, p. 102), and as I have been a teacher and tutor for this diploma over a period of years my remarks may be of value to him, and to other officers contemplating obtaining it. I agree that the standard of the examination has required improvement, but actual preparation time remains about the same, as much obscure psychology and physiology has been eliminated or has at least ceased to figure in the actual tests. In Part II the psychiatric examiners are, by their writings and practice, acknowledged as experts in all phases of mental disorder, keep well within the scope of the prescribed syllabus, and maintain a very fair balance between the various subdivisions of the specialty in their questions. I am convinced most holders of the Diploma wish to feel they are recognized to advise expertly in the widest conception of psychological medicine, and not in the limited mode your correspondent suggests. Undoubtedly the standard in neurology is especially high, but as more and more of us are wont to describe ourselves as neuropsychiatrists, it is well this designation is not assumed, unless our ability is well proven. With reference to general practitioners and the Diploma, I can state that I have coached many while they have been carrying on their practices, and their pass record has been most creditable. My chief complaint about the examination concerns Part I, which is still far too academic, of no value to the candidate for his future practice, and is a real deterrent to those of more mature years contemplating the course of instruction. I strongly recommend your correspondent to have a "stab" at the examination as soon as possible: I am sure he will find many of his "notions" ill founded.

Warts

Dr. T. C. GIPSON (Pinhoe, Devon) writes: In "Any Questions?" of July 22, under the heading "Warts," the advice given for treatment of a doctor's child for wart on the knee is to apply formalin for fifteen minutes daily. Surely this is unnecessarily protracted in a doctor's household. A very much quicker method is: Surround the wart with a trace of vaseline or ointment, and apply concentrated nitric acid with a match so as to leave a definite bead of wet fuming acid on the wart; keep the child with the leg up until the acid has dried off; a little smarting will be felt after five minutes. Next day the top of the wart is cut off with an old razor blade until the roots show unstained yellow; another application with a match-stick, which will sting for ten minutes, and the wart is finished. N.B.—In cutting off the dead wart it is important to stop before bleeding occurs because this dilutes the acid on the second application. Incidentally, it is painless as long as the wart is deeply stained.

Correction

We apologize for the error which crept into the annotation on "Nutrition and the War" published in the *Journal* of July 15 (p. 84). Dr. Sydenstricker did not observe that it was "a pity that the pregnant woman does not get her unborn child's ration book as soon as she is pregnant instead of ten months later." Since July 25, 1943, the pregnant woman has in fact been entitled to her unborn child's ration book as soon as pregnancy is established and she makes application to the Food Office.

BRITISH MEDICAL JOURNAL

LONDON SATURDAY AUGUST 19 1944

SCURVY: A SURVEY OF FIFTY-THREE CASES

BY

R. B. McMILLAN, M.D., B.Sc., M.R.C.P.Ed.

Medical Superintendent, Eastern General Hospital Edinburgh

AND

J. C. INGLIS, M.B., Ch.B.

Late Senior Medical Officer, Eastern General Hospital Edinburgh

Between Aug, 1937, and Feb, 1944, inclusive, 53 patients with scurvy—48 males and 5 females—were admitted to medical wards in an Edinburgh municipal general hospital. The annual number of cases, and the percentage they formed of all medical admissions, are shown in Table I.

TABLE I

Year (Aug-July)	Cases of Scurvy			Nos. all Medical Admissions			% Incidence Scurvy		
	M	F	Total	M	F	Total	M	F	Total
1937-38	3	—	3	1,055	767	1,822	0.28	—	0.16
1938-39	6	—	6	833	533	1,416	0.71	0.17	0.49
1939-40	5	—	5	649	489	1,138	0.77	—	0.44
1940-41	8	1	9	378	246	624	2.11	0.41	1.44
1941-42	18	2	20	368	283	651	4.89	0.71	3.07
1942-43	8	1	9	459	360	819	1.74	0.28	1.09
1943-44	—	—	—	682	599	1,281	—	—	—

The patients ranged in age from 41 to 82 years. Including the 5 women, 43 were aged 65 or over. Eight of those under 65 were admitted in 1941-2. Fifty-one lived alone (single 27, widowed 17, separated 7), two were married and lived at home. Lodging conditions were: working men's hostels, 28, private houses, 13, furnished rooms, 8, living with relations, 3, lodgings with board, 1. Forty-eight cooked for themselves, this total including one of the married men who kept house for his wife, who worked and had her main meal out daily. Fifty gave satisfactory details about income. Thirty-four were dependent on an old age pension plus a supplementary allowance which increased with the rising cost of living, giving totals varying from 13s to 22s 6d a week. Thirteen were dependent on private pensions varying from 5s house-free to 39s 5d a week, 10 of them having 25s a week or more. Three were in gainful employment with 60s to 80s a week. From details given regarding expenditure on lodgings (30 to 40% of incomes under 25s a week), clothing, tobacco, and alcohol (heavy in three instances only), the income remaining for food per week was calculated. Twelve had 8s a week or less, 13 of whom 7 were admitted before Aug, 1940, had from 8s to 10s a week; 25, admitted with one exception after Aug, 1940, had 10s a week or more. Eighteen had not sufficient to buy a diet adequate in proteins, fat, calories, and vitamins, assuming 8s a week to be necessary for this until July, 1940 and 10s a week thereafter (Orr, 1937). Dietary histories showed that the intake of potatoes and vegetables was low in all cases and very low in some. Approximately two-thirds ate fruit—most of them irregularly—when it was obtainable. Patients from this group were naturally admitted in great numbers after 1940 and provided the bulk of the cases seen. They had mainly adequate food incomes. One patient ate regularly in a British Restaurant; six others did so very spasmodically. A few in 1941-2 complained of the high cost of vegetables. Two men who were working said that the shops were closed when they were free to shop. Many complained of lack of cooking facilities in their lodgings. One individual—the remaining married man—had been carefully adhering to a vitamin-deficient diet which had been prescribed for him for

a gastric condition. Physical or mental defects were present in six instances, but in four these coexisted with food incomes of 8s a week or less.

Clinical Notes

The disease developed most commonly in June, then came May, March, and April in that order. No case began in July, and few in the remaining months of the calendar year 1941-2 showed an unusual feature with admissions in Nov. and Dec, 1941, and Jan and Feb, 1942. The time elapsing between the first sign or symptom and admission to hospital was less than one month in 80% of cases. Few arrived within one week and only one after 18 months. The disease, by the usual standards, was mild in 2 instances and moderate in 51. All patients had skin petechiae. In two these were the only sign. Fifteen had deeper haemorrhages in one leg, 23 in both legs, and 13 in both arms and legs. Where teeth existed spongy and infected gums were very common. Bleeding gums were noted on 8 occasions, being present only in association with gross changes elsewhere. The onset and progress of the disease were typical, it appeared first in one leg, then the other, and finally the arms. Discomfort was usually mild at first, but became progressively more severe, within a month most patients were crippled, and were pleased to be allowed to rest in bed. One patient had epistaxis, another intestinal colic with melaena and three of the most severe had histories of intestinal colic alone. Frank lower-bowel haemorrhage or haematuria was never encountered. "Lumbago" was experienced by three individuals just before the leg symptoms were noted. One female developed a large haematoma of the forearm after a Hess cuff test had been done. Poor wound-healing was noted and reported elsewhere (McMillan, 1943). None of the patients had clinically evident cataracts. Fractional test meals were carried out on 10 patients. The results and the blood findings are given below. In 50 patients the haemorrhages appeared spontaneously. In 3, trauma, by causing grossly excessive bruising, drew attention to the deficiency. One individual, who developed the disease after being confined to bed for six weeks, had haemorrhages on the buttocks only, the legs being unaffected.

Multiple neuritis (3 males) and pellagra (2 males and 1 female) were also recognized clinically. Hyperkeratosis perifollicularis was very common but not universal.

Chemical and Other Tests

1. Cuff Test—Positive-pressure cuff tests—Hess (Hess, 1920) or Gothlin (Falk *et al.*, 1932)—were done on 40 patients before and after saturation with ascorbic acid. Of 22 tested by Hess's method 14 were positive before and negative after saturation, 4 positive before and after, and 4 negative before and after. Of 18 by Gothlin's method, 7 were positive before and negative after, 2 positive before and after, and 9 negative before and after. Neither test was diagnostic, but the Hess method gave a higher percentage of the usually expected result. The results by either method were unrelated to the plasma ascorbic acid level or the saturation requirements.

2. **Vitamin C Content of Urine** (using the dichlorophenol-indophenol indicator).—The urine passed by the patients during their first 24 hours in hospital was collected, stored with due precautions, and examined. The vitamin C content varied from 1.5 to 16 mg., averaging 7 mg. Thirty of them were then tested for deficiency by one of three methods ((a) Abbasy *et al.*, 1935; (b) Eddy and Dalldorf, 1941; (c) Harris and Abbasy, 1937). All were deficient. Further ascorbic acid was then given, in the manner recommended, until saturation was achieved. The results are shown in Table II. There was no steady relationship between the saturation requirements and the clinical extent of the disease.

TABLE II

Method	Amount (g.) Ascorbic Acid required for Saturation								Average (g.)
	2-2.4	2.5-2.9	3-3.4	3.5-3.9	4-4.4	4.5-4.9	5-5.4	5.5-5.9	
(a) ..	1	2	4	4	1	—	—	—	3.18
(b) ..	—	—	1	1	2	—	—	3	4.5
(c) ..	—	1	—	2	—	5	1	—	4.1
Total	1	3	5	7	3	6	2	3	3.85

3. **Plasma Ascorbic Acid Content.**—This estimation was made on 22 patients within 48 hours of admission. All had levels compatible with clinical scurvy—e.g., eight had 0 to 0.04 mg. %; two, 0.05–0.09 mg. %; five, 0.10–0.14 mg. %; four, 0.15–0.19 mg. %; two, 0.20–0.24 mg. %; and one, 0.25–0.29 mg. %. An inconstant relation existed between these figures and the clinical picture, but not to the saturation requirements.

4. **Blood Tests.**—Bleeding time (Dukes's method), 1½ to 3 minutes. Coagulation time (capillary tube with normal control), 3 to 9 minutes, but never longer than the control. Platelet count (dry smear), 120,000 to 340,000 per c.mm.

Blood Picture

A complete blood examination was conducted on 38 males and 2 females within 48 hours of admission. Red cell counts ranged from 1,730,000 to 5,220,000 per c.mm., with 65% of all counts above the 3,000,000 level. Two males had no oligocythaemia. Haemoglobin ranged from 38 to 85% (Sahli), and from 5.3 to 11.9 g. per 100 c.cm. The mean corpuscular haemoglobin (M.C.H.) varied from 16 to 38γ. White blood cell counts ranged from 2,800 to 12,000 per c.mm. Erythrocytes were mainly normal in size and shape, anisocytosis being noted in approximately 20% of smears and being much more common than poikilocytosis. Ring staining was observed on three occasions. Nucleated red cells were never seen. Reticulocytes ranged from 0.5 to 1.5% with one exception, in which they were 4%, the patient actively losing blood from haemorrhoids. The morphology of the leucocytes was not specially noted. The sternal marrows of 6 patients were examined: five were normoblastic, one megaloblastic. Two of the former showed a few megaloblasts. The presence of megaloblasts was associated with achylia gastrica in two instances and a low free HCl in another. One patient with a markedly macrocytic anaemia and a normoblastic marrow had normal test-meal findings (Case 3, Table IV). Short details relating marrow and blood pictures are given in Table IV.

A morphological classification of the various anaemias was made, using the red cell count and the M.C.H. of each case. The place allocated to the 6 fully investigated cases was then checked, and it was found that only one had been placed wrongly—as "slight simple microcytic" instead of "moderate normocytic." With this error corrected the table is reproduced below (Table III), and it is submitted that any error in it lies in the existence of an inflated "simple microcytic" group at the expense of the "normocytic" group.

TABLE III.—Morphological Classification of the Anaemias in 40 Scurvitic Patients (after Wintrobe, 1942)

Type	Degree	No.	Type	Degree	No.
Macrocytic	Slight ..	0	Simple microcytic	Slight ..	4
	Moderate ..	2		Moderate ..	10
	Severe ..	0		Severe ..	0
Normocytic	Slight ..	10	Hypochromic microcytic	Slight ..	4
	Moderate ..	8		Moderate ..	2
	Severe ..	0		Severe ..	0

The anaemia present bore no constant relation to the extent of haemorrhages or to the plasma ascorbic acid content or saturation requirements of the patients. It was varied in type, being mainly normocytic, rarely hypochromic microcytic, and more rarely macrocytic.

Treatment

This was dictated at times by experimental needs. The administration of ascorbic acid in addition to the ordinary hospital diet always resulted in quick improvement. Appetite improved, pain and stiffness in the legs disappeared, and within a week the patient felt very well. This change was commented upon by some of the sufferers, who said they "had not been so well for years."

Particular attention was paid to changes in the blood picture during treatment. Six clinical experiments were designed to elucidate certain points. To save space the observations made have been condensed as much as possible. The blood pictures and the results of treatment of the 10 patients who form the basis of experiments 3 to 6, inclusive, however, were considered interesting enough to be given (see Table IV). Reference to this table is made in the text which follows. It will be noted that the columns for red cell count, Hb, etc., have been subdivided into five. Findings, at any one time in any case, are given in the correspondingly numbered sub-column—e.g., the blood picture in Case 1 on admission can be obtained by reading all the figures in sub-columns 1, and so on. The experiments were consecutive, and the final blood figures in experiment 3, shown in sub-column 2, are the initial figure for experiment 4, the final figures for which are shown in sub-column 3, and so on. Lastly, in order that the duration of each clinical test could be shown, bracketed figures, giving the time in days, have been placed above the red cell counts.

Exp. 1.—Four patients with anaemia ranging from 2,490,000 R.B.C. per c.mm. and 42% Hb to 3,350,000 R.B.C. per c.mm. and 62% Hb were placed on the ordinary hospital diet containing a calculated vitamin C and iron content of 15 mg. and 14 mg. daily respectively. Red cell and Hb regeneration began immediately, a reticulocytosis of 4% being noted in two of the cases.

Exp. 2.—Eleven patients with anaemia ranging from 2,200,000 R.B.C. per c.mm. and 40% Hb to 4,670,000 R.B.C. per c.mm. and 85% Hb were given the same diet (approximately) plus 500 mg. of ascorbic acid daily by mouth until saturated, and thereafter a maintenance dose of 100 mg. daily. Red cell and Hb regeneration again began immediately, and continued until the anaemia was cured. Reticulocytes never rose above 2% in any instance. Over all, the response was as good as in the case of the four who were not given ascorbic acid. In general, the more severe the anaemia the more rapid the rate of red cell and Hb regeneration: Falling M.C.H. values in a number of cases suggested that extra iron would have been advantageous.

Exp. 3.—Ten patients, details of whose blood pictures are given in sub-columns 1 of Table IV, were placed on a vitamin-C-free diet. This consisted of well-cooked meat, tripe, rabbit, chicken or fish, fried bacon, powdered egg, porridge, boiled rice, semolina or custard, bread, margarine, cheese, cocoa or tea. No soups or vegetables, or foods cooked with vegetables, were permitted, and the 4½ pint daily milk ration was heated to 100° C. for 20 minutes and cooled before issue. Extra vitamins were added by giving 1 drachm Halibol and 6 pulvules of Betalin Co daily by mouth. Clinical experience of this diet indicated that it contained little or no vitamin C. Its calculated iron content was 6 mg. daily.

The blood pictures of these patients after periods ranging from 9 to 14 days on this diet are given in column 2 of Table IV. Briefly, 5 patients showed increase in red blood cells and Hb, the rate of improvement varying considerably. The remaining 5 showed no change in their red cell count, the Hb also remaining stationary in all but one, in whom it rose 10%. Reticulocytes rose to 4% in one of the patients showing improvement; the others never rose above 1.5%.

Exp. 4.—Six of these patients (Nos. 1, 2, 3, 4, 6, and 7 in Table IV) were kept on the vitamin-C-free diet for further periods, with the addition of 18 gr. of ferrous sulphate daily by mouth, ac. hydrochlor. dil. m. 60 i.i.d. with meals being given also to those with achlorhydria. The blood pictures at the end of this test are shown in sub-columns 3 of Table IV. The red cell count rose in five but remained stationary in one. The Hb rose in all. The patient whose

* Represent vitamin A 60,000 I.U., vitamin D 10,000 I.U., thiamin 6 mg., riboflavin, 1,998 gamma, nicotinic acid 12 mg., pyridoxine 1,200 gamma, plus other factors of vitamin B complex from liver-stomach concentrate and a negligible amount of anti-anaemic factor.

red cell count remained stationary had shown improvement on the previous diet. Two now improving were doing so for the first time, but, as one had a peak reticulocytosis of 3.5% three days after iron was added, the improvement was judged to be a delayed response to the earlier treatment. In the other it may have been likewise. Reticulocytes, except as above, remained below 2%.

Exp. 5.—The same 6 patients were used in this test, their treatment being altered only by the administration of 500 mg. of ascorbic acid daily by mouth until saturated and thereafter a maintenance dose of 100 mg. daily for the remainder of their varying test periods. Their final blood pictures are given in sub-columns 4 of table IV. The red cell count rose in five and the Hb in four. In the cell count and Hb in those not improving (Cases 1 and 2) were already high when the test began it was thought that they had already reached their maxima. The individual whose blood picture had improved and then remained stationary in the two previous tests now showed a marked improvement, and had a 4% reticulocytosis on the sixth day. Reticulocytes otherwise remained under

the diet. Second was apathy leading to neglect of the same items because they required preparation and cooking. Third was poverty, making it impossible to buy an adequate diet or live anywhere but in the worst type of lodging with poor cooking facilities. The first was not so significant in peacetime, as many countered it by eating fruit. Wartime scarcity of fruit without a compensatory increase in the intake of potatoes and vegetables resulted in such individuals developing scurvy. This group, often younger and better off than the usual scorbutic, was responsible for most of the increase in the disease in 1940-1-2. What probably happened was that those dependent on fruit developed scurvy quickly and were admitted in 1940-1. Those less dependent developed it more slowly and were not admitted until 1941-2, appearing out of the usual season in many instances. This group was the greater, and 1941-2 had many more admissions than 1940-1. In 1942-3

TABLE IV

2%. Absolute blood findings were by now normal or nearly so. The original megaloblastic marrow was now normoblastic.

Exp. 6.—Four patients (Nos. 5, 8, 9, and 10, Table IV), originally on the vitamin-C-free diet and referred to in experiment 3, were given, at the end of that experiment, ascorbic acid by mouth in saturating doses as detailed before, and thereafter the usual 100 mg. daily maintenance. Their blood pictures at the conclusion of this test are shown in sub-columns 5, Table IV. The red cell count rose in three and remained stationary in one. The Hb rose in all—slightly in one showing a good red cell rise. Improvement began only after two or three days, and was slow initially, accelerating later. Reticulocytes never rose above 2%. The patient whose red blood cells failed to rise (No. 10) later resisted liver injections, thyroid, etc., and the opinion was formed that his marrow was hypoplastic.

As no patient on the C-free diet showed a drop in either red cell count or Hb, regeneration, however slow, must have been going on. Lack of vitamin C alone in the diet did not prevent blood formation. In most individuals its presence accelerated regeneration. For this action little seemed to be required, as it was supplied by an ordinary mixed hospital diet. Iron lack was not a serious factor in the majority of cases investigated.

The anaemias investigated were nutritional in origin. The main causal factor was contained in the vitamin-C-free diet. Lack of vitamin C alone was not the cause of the anaemias, although it might have helped in their development. Iron lack played a minor part.

Discussion

The disease observed was typical "bachelor" scurvy. There were three root causes. First and most important was ignorance, mainly in males, of the need for potatoes and vegetables in

two patients only of this type were seen, and as a result the total for the year was low. The inference was that a lesson was being learnt and that such individuals were eating more potatoes and vegetables, so that vitamin C intake, which deteriorated in the two years after 1940, when shortages and rationing first became apparent, was improving. As this seemed important an attempt was made to define the position in Edinburgh and Glasgow by obtaining from the Municipal General Hospitals and the Royal Infirmary, Edinburgh, and the Municipal General Hospitals and the Western, Royal, and Victoria Infirmarys, Glasgow, the number of scorbutics treated by them over the same period. The results (Table V) showed the same rise and fall as in the local observation, and it is suggested that the same reason also holds.

TABLE V

Aug.-July, Year	Col 1: Edinburgh			Col 2: Glasgow	
	Scurvy Nos.	% Medical Admissions	Rate per 100,000 Pop.	Scurvy Nos.	Rate per 100,000 Pop.
1937-38	11	0.11*	2.35	24	2.14
1938-39	23	0.25*	4.89	36	3.19
1939-40	13	0.16*	2.75	28	2.48
1940-41	27	0.36	6.55	40	3.83
1941-42	45	0.61	10.52	66	6.31
1942-43	26	0.35	6.03	50	4.78

* Note.—Percentage incidence of scurvy to medical admissions in Glasgow hospitals not shown, as data of total medical admissions could not be obtained.

* Cf. 0.14% in Boston City Hospital over the period 1930-9 (Faulkner, 1941).

The close similarity between Edinburgh and Glasgow is capable of explanation by the fact that both have approximately the same intake of vitamin C per head of the population (personal

communication from the Ministry of Food). This intake is much below the average for all towns in Britain, and therefore the figures for vitamin C nutrition elsewhere are presumably better. The percentage incidence of scurvy of all medical cases in Edinburgh is much lower than in the hospital in which the investigation was made. This hospital serves mainly the elderly poor, whose vitamin C nutrition is probably lower than that of other classes of the population.

The improvement noted must be credited to the activities and propaganda of the Ministry of Food. Nevertheless it is suggested that so long as the scarcity of fruit exists the concessions at present enjoyed by children and expectant mothers should be extended to the elderly. Scurvy, which is only one evidence of faulty nutrition among the aged poor, will need more than propaganda for its abolition, and it is suggested that the provision for them of clean cheap lodgings, with canteen facilities and very discreet supervision, is one which local authorities might consider as the most practical step.

Clinically the only unusual complaint was lumbago, which it is suggested was the result of small deep haemorrhages in the muscles of the back, and indicates an unusual cause for this complaint in poorly nourished individuals.

The anaemias in the cases investigated showed no new factors so far as the peripheral blood was concerned. Although in no patient was the blood picture completely normal, in some it was very nearly so, and agreement is reached with the opinions of others that (a) anaemia and scurvy need not coexist in man (Crandon *et al.*, 1940); (b) when they do coexist the anaemia often bears no relation to the extent of the haemorrhages or the plasma ascorbic acid content (Croft and Snorf, 1939); and (c) the anaemia is varied in morphological type, being mainly normocytic (Parsons and Smallwood, 1935). The marrow findings were also similar to those recorded by others. These earlier findings were: (a) a gelatinous mass with failure of erythropoiesis (1 case) (Harris, 1927-8); (b) moderate hyperplasia with scattered small groups of erythroblasts and no fibrosis (1 case) (Mettier *et al.*, 1930); (c) one normal marrow, and one megaloblastic marrow associated with macrocytosis and achylia gastrica (Jennings and Glazebrook, 1938); and (d) one normal marrow and two showing diminished erythropoiesis (Israëls, 1943). The change from a megaloblastic to a normoblastic type with only dietary replacements was interesting. This has been noted in non-scorbutics with nutritional anaemia with (Groen and Snapper, 1937) and without (Napier *et al.*, 1938) free HCl in their gastric juices. The inference is that the marrow changes in scurvy are not specific.

As regards the cause of the anaemia of scurvy many views have been expressed. In 1930 it was thought confidently that there was a specific anaemia due to vitamin C deficiency (Mettier *et al.*, 1930). Since then, however, many observations have been made. The following are noteworthy: (a) vitamin C lack will not affect blood formation (Crandon *et al.*, 1940); (b) Hb and red cell regeneration with reticulocytosis occurs in scorbutics on a vitamin-C-free diet (Lozner, 1941; Ungley, 1938); (c) ascorbic acid has failed to cure an anaemia in experimental scurvy which did react to germinated oats (Aron, 1939); (d) vitamin C was necessary in one deficient individual to prevent the progress of the anaemia (Vaughan, 1934); (e) vitamin C is necessary in some deficient individuals before the anaemia will respond to treatment (Kenney and Rapoport, 1939; Dyke *et al.*, 1942). Belief in the need for vitamin C has therefore dwindled, and it has been suggested that the anaemia of scurvy is due to lack of other factors (Croft and Snorf, 1939). The present experience confirms points a, b, and e.

Lastly, as the anaemia of scurvy is due to a complex deficiency, with vitamin C acting only as an adjuvant, and as it is usually moderate in degree, the often-observed absence of reticulocytosis is not surprising. To obtain it, even where the anaemia is severe enough for a good reticulocyte response to be expected, it would be necessary to supply all deficient factors at once—a form of treatment rarely given.

Summary

The social and economic backgrounds in 53 adults with scurvy are detailed, with clinical features including blood changes and biochemical findings.

The causes of scurvy of this type are assessed as ignorance, apathy, and poverty.

The incidence of scurvy in the series is compared with the percentage for the main hospitals in Edinburgh and Glasgow for each year from mid-1937 to mid-1943. The significance of the figures is discussed.

A morphological classification of the anaemia of scurvy is made. The type of sternal marrow in six cases is indicated broadly. The anaemia is shown to be nutritional in origin and to be capable of alleviation in the absence of vitamin C, which is, however, thought to act as an adjuvant to the regenerating factors.

Suggestions are made for the elimination of scurvy.

We wish to acknowledge our indebtedness to Dr. W. G. Clark, medical officer of health, City of Edinburgh, for permission to publish this paper on patients in hospitals under his control; to the medical superintendents of the Edinburgh and Glasgow hospitals named in the text for their co-operation and active help in obtaining statistics; to Sir Jack Drummond, Scientific Adviser, Ministry of Food, for very useful confidential information on present-day vitamin C nutrition; and to Miss Agnes Hughes, ward sister, Eastern General Hospital, Edinburgh, for supervising the majority of patients and controlling the experimental diets.

URTICARIAL REACTIONS AND DESENSITIZATION IN ALLERGIC RECIPIENTS AFTER SERUM TRANSFUSIONS*

BY

KATE MAUNSELL, M.D.Kiel, L.R.C.P.Ed.

While a great deal of research has been done on the haemolytic and the pyrogenic transfusion reactions, less attention has been paid to the so-called "allergic reactions." They are said to occur in about 1% of transfusions (Wiener *et al.*, 1941; Hoxworth and Skinner, 1941), and the incidence seems to be the same whether blood or plasma or serum is administered.

Immunologically the word "allergy" covers the changes in reaction towards increased and reduced sensitivity due to the presence of acquired antibodies. Clinically, however, the term "allergic transfusion reaction" is used, in a more restricted sense, for the occurrence of such phenomena as urticaria, angioneurotic oedema, bronchial asthma, and, in rarer instances, shock. It is commonly assumed that the cause of these syndromes lies in the transfusion of blood from the allergic donor to the normal recipient (*Lancet* editorial, 1941; Colonnell, 1943). Scarcely any attention has been paid to the role of the allergic recipient in the production of transfusion rashes, and only one case report of an allergic recipient developing a transfusion rash was found in the literature (Stewart and Bates, 1938). Neither is it yet established whether the first transfusion sensitizes or desensitizes the reacting recipient for subsequent transfusions with human material. Whereas Gyorgi and Witebsky (1929), Wiener *et al.* (1941), and Kilduffe and De Bakey (1942) believe in the development of an allergic supersensitivity in the interval between repeated transfusions, Young (1942) reported apparent desensitization.

* A report to the Medical Research Council from the S.W. London Blood Supply Depot.

The chief purpose of the present research was therefore to investigate the response of the allergic recipient to injection of human serum and to observe his behaviour to repeated transfusions. The investigations have been carried out in two sections. The first deals with skin tests by allergens and serum, the second with serum transfusions.

One type of human allergy, "atopy," has been investigated in regard to transfusion reactions. The term "atopy" has been introduced by Coca *et al.* (1931) to separate a certain group of allergic manifestations from the hypersensitiveness of infection and horse-serum disease. The term designates such forms of hypersensitiveness as urticaria, bronchial asthma, and vasomotor rhinitis, which have a hereditary basis and in which the hypersensitivity is characterized by special antibodies, the reagins. Reagins are present in the circulating blood, and are capable of sensitizing mucous membrane and skin in such way that the minute vessels quickly produce an urticarial reaction on contact with the atopens. The best-known atopens are pollen, dust, milk, and egg. Reagins are transferable to normal individuals, sensitizing their skin and their mucous membranes.

Cases

The subjects were divided into three different groups.

Group I: Cases of Bronchial Asthma and Hay-fever (Atopic Types).—A family history of allergy was usually present. The patients, whose ages ranged from 11 to 43 years, gave positive skin reactions to one or more of the tested atopens. Reagins could be determined by passive transfer.

Group II: Cases of Bronchial Asthma (Non-atopic Types).—That this group is distinct from the first is shown by the usual lack of an allergic family history, the higher age group of the patient, negative tests with atopens, no determination of reagins, and the high incidence of chronic respiratory-tract infection.

Group III: Normal Controls.—These subjects gave no allergic family history and did not complain of any atopic symptoms. Atopic tests were negative.

Persons with latent allergy were excluded in this study—i.e., subjects with positive skin reactions but with no clinical history of allergic phenomena.

Part I: Skin Tests

Method.—Dried pooled human serum was reconstituted to normal strength with distilled water and filled into sterile test-tubes of approximately 2 c.cm. content. These test-tubes were kept frozen at 5° F. till required. On the day of use one or more of these tubes were thawed out and a sterile tuberculin syringe was charged with the fluid. To avoid any risk of contamination each tube was discarded after having been opened. Each syringe was used for one tube only, and after use was cleansed in chromic acid and reesterilized. For the test, two intracutaneous injections, each of 0.05 c.cm. of the reconstituted serum, were made into the skin of the back in parallel with extracts of mixed inhalants and food in appropriate concentrations and 0.5 c.cm. of carboll saline. Whenever it seemed necessary, single atopic extracts were used.

Estimation of the Skin Reaction for Serum.—The intradermal injection of 0.05 c.cm. of serum produced a raised bleb of 0.8 cm. diameter in each person immediately. A bright flare of about 2 in. diameter occurred around this site of injection and faded after 10 to 15 minutes. A slight wheal formation was often noted as a semilunar swelling of the injected bleb. A reaction of this kind was recorded as negative. The reaction was regarded as positive when the erythema covered a larger area and was still present after twenty minutes, and when, simultaneously, the wheal developed in the whole circumference of the bleb. The size of the wheal was measured after 30 minutes by pressing a glass slide against the skin, and the outlines thus demarcated were arbitrarily recorded as:

Reaction	Largest diameter of wheal:	1-1.5 cm.
..	1.5-2 cm.
..	more than 2 cm.

It should be made quite clear that a positive reaction was estimated by a quantitative difference and not by a qualitative variation. The method was not found reliable enough to estimate fine gradations, as even with careful work a different reaction was sometimes obtained from two equal injections. Two to three hours after the injection the wheal turned brownish. It usually disappeared within 24 hours. Late reactions in the form of distinct papules were observed rarely when working under strictly sterile conditions.

Results

Series 1: Sensitiveness to Reconstituted Dried Pooled Human Serum (Table I).—Group I: Of 52 atopic patients 40 (77%) gave positive serum tests, 3 of them being ++, 12 +, and 25 -. Group II: Of 25 persons only 5 (20%) showed positive

serum reactions; they were of the low grade. Group III: Of 50 persons 10 (20%) gave positive serum reactions, all of them being of the low grade.

TABLE I.—Skin Reactions to Intradermal Tests with Reconstituted Dried Pooled Human Serum

	Group I: Br. Asthma, etc., Atopic Type	Group II: Br. Asthma; Non-atopic Type	Group III: Normal
No. tested	52	25	50
Negative reactions	12	20	40
Positive reactions	25 12 } 40 3 }	5 — } 5	10 — } 10

It will be noted that there was a striking contrast between the atopic and non-atopic subjects in their susceptibility to serum tests.

Series 2: Sensitiveness to Fresh Unpooled Human Serum (Autoserum and Iso-serum).—Blood was collected into sterile centrifuge tubes from 36 donors and kept at 4° C. for one day. The serum was then pipetted off after centrifugation. It was kept frozen solid until used for testing, which was usually done two days after bleeding. Thirty-six subjects of the atopic and non-atopic types were tested with their own fresh serum (autoserum), with three or four fresh sera from other individuals—also of atopic and non-atopic groups (isoserum)—and with one pool of dried serum. Autoserum did not cause a reaction in any of the 36 recipients. Iso-serum, on the other hand, did give reactions in some cases, which also reacted to pooled serum. These positive cases were, as before, in the main atopic subjects. In any one person the reactions to various individual sera were not all equally strong. Furthermore, a single serum which gave the strongest response in recipient X. did not necessarily do so in recipient Y., and vice versa. Positive reactions were not obtained more often with sera from atopic donors than with sera from non-atopic subjects.

Series 3: Sensitivity to Fresh Human Sera of the Four Main Blood Groups.—Three sets of sera were obtained in the same way as in Series 2. A set consisted of four sera—one each of the four main blood groups, AB, A, B, O. For testing each set 12 recipients (both atopic and non-atopic) were chosen, so that there were three individuals of each of the blood groups. Some of the recipients, especially of groups B and AB, were used for testing more than one set, but on different days. Positive reactions occurred in 11 recipients—1 out of 6 AB, 4 out of 12 A, and 6 out of 12 O. The sensitive individuals gave more or less strong positive reactions with all four sera of the main blood groups. The results therefore show no relation between the blood groups of donors and recipients. Of the 11 serum-sensitive recipients 9 suffered from bronchial asthma and hay-fever.

Part II: Transfusions

The fact that 80% of atopic individuals were positive to serum tests suggested that urticarial rashes after serum transfusions might occur more often in such subjects than in other persons.

Method.—Two pools of dried serum, each consisting of about 60 bottles, were used so that a number of atopic subjects and non-atopic controls could be transfused with the same serum. One bottle was reconstituted to normal strength with 400 c.cm. of distilled water. The serum was administered as soon as the dried powder had dissolved completely. Adjustment of the duration of the transfusion to 25 to 30 minutes was aimed at, but in patients who were known to have a high degree of atopic sensitiveness the first transfusion was given at a much slower rate. Whenever a rash appeared during the administration of serum the transfusion was stopped immediately. All persons transfused had been tested previously (Part I). If possible, the test injection of pollen, dust, etc., was avoided on the day of the transfusion, whereas serum tests were frequently applied simultaneously with the transfusion. The transfused persons were under constant observation during the transfusions, and were seen at least two to three times in the next three hours. The temperature and pulse were recorded half-hourly. No transfusions were administered during attacks of bronchial asthma.

Estimation of the Transfusion Reaction.—Up to half a dozen solitary small wheals occurred so often during or after transfusion that they were not considered to be a transfusion reaction. The features of what was regarded as a positive transfusion reaction were a large number of solitary white wheals surrounded by red flares, or many wheals occurring in large erythematous areas. Sometimes the wheals ran together and formed large white oedematous zones. The wheals tended to occur on the back, round the neck, and on the face. It was often noted that the first whealing appeared in areas in which the skin was subjected to pressure. The wheals were usually preceded by itching, which increased in intensity so long as fresh wheals were forming in the skin. In some patients running of the nose, streaming of the eyes, and tightness of the chest

occurred simultaneously. The general condition of the patient was in the majority of cases not affected by the transfusion reaction and no adrenaline was necessary to control the symptoms. Attacks of bronchial asthma were rare, but they were observed even in subjects who had previously suffered only from allergic rhinitis. Very occasionally the rash was accompanied by a marked fall of blood pressure and increase of pulse rate. This state of collapse was successfully treated with adrenaline. The transfusion reactions were recorded as:

Reaction	+	..	Erythematous patches and 6 to 20 isolated wheals
"	++	..	Erythematous and more than 20 isolated wheals
"	+++	..	Erythematous and numerous confluent wheals
"	++++	..	Collapse in conjunction with rash

The time of onset of a transfusion reaction was in distinct relation to the severity of the attack, the strongest rashes occurring after the shortest incubation period. The majority appeared 10 to 30 minutes after the end of the transfusion, but in a few cases the outbreak was observed one to two hours later. The most severe reactions came on during the administration of the fluid. The duration of a weak reaction was not longer than half an hour, but stronger rashes lasted one to two hours. Rigor and rise of temperature occurred independently of the rashes.

Results

Series 4: Reactions to First Transfusions (38 Cases, Table II).—17 atopic subjects of Group I, 9 patients of Group II, and 12 persons of Group III were transfused each with 400 c.cm. of reconstituted dried pooled serum. **Group I:** Of the 17 patients 14 developed an urticarial rash (2 +++++, 5 +++, 4 ++, 3 +). Only two of the recipients had reactions of the violent type. One occurred in a boy aged 10, with bronchial asthma, who was sensitive to dust and related inhalants. The urticarial rash developed during the transfusion, after 300 c.cm. had been administered. The boy shortly afterwards complained not only of an attack of asthma but of severe abdominal cramps. These were accompanied by a den fall of blood pressure. The reaction was controlled by renaline. The other alarming incident occurred in a young woman aged 26. She suffered from bronchial asthma and was extremely sensitive to egg. After 100 c.cm. of serum had been given her eyelids started to itch and swell. The transfusion was stopped, but the patient became deeply cyanosed. The pulse was 140 and the blood pressure 80/50. She recovered from the atopic shock after treatment with adrenaline and cardophyllin, but suffered from an asthmatic attack for the next three hours. Both these cases had only moderately strong positive serum skin reactions, whereas other persons with much more pronounced skin reactions produced general manifestations of a weaker degree. **Groups II and III:**—Twenty-one subjects were transfused, and no rash was observed in any of the cases.

Series 5: Reactions to Subsequent Transfusions (22 Cases, Table II).—The same pool which had been used for the first transfusion was administered on a second and a third occasion. The interval between the transfusions was usually a fortnight. **Group I:**—A second transfusion was given to 14 patients, 11 of whom had

developed a rash on the first occasion. After the second treatment 10 out of these 11 showed definite signs of desensitization: 6 subjects had no reaction at all, 4 got a slight rash, and only 1 reacted in the same way as on the first occasion. A third transfusion was given to 8 subjects, all of whom had produced urticaria when transfused for the first time. Of these cases 7 demonstrated the decrease of sensitivity—5 did not react at all, and 2 showed some erythematous areas but no wheals. Only one boy, aged 11, again developed a rash. Three patients who had been desensitized by repeated transfusions of serum from the same pool were re-transfused with serum of other pools. No reaction occurred. Thus desensitization had been established not only for the pool which had been given during the course of transfusions but also for others. Three patients who did not respond to the first transfusion were equally negative on re-transfusions. **Groups II and III:**—Eight cases were re-transfused and were negative as on the first occasion.

The marked decrease of urticarial rashes in sensitive individuals on repeated transfusions demonstrated the desensitizing power of serum transfusions.

Skin Tests Before and After Transfusion.—Two tests were made with pooled serum. The first was carried out in the recipient 20 minutes before starting the transfusion, and the second was performed towards the end. There was hardly any difference in the reaction in those cases which failed to produce a rash. In those individuals, however, who subsequently developed a rash, the second reaction was about five times as large as the first. It was formed not only by increase of the original bleb but also by coalescence of small wheals which developed in the area of the erythema. This phenomenon, when observed, preceded a general reaction by 10 to 30 minutes.

Discussion

The occurrence of urticaria after transfusion is accepted mostly, without further comment, as an allergic reaction, but the validity of such an assumption seemed doubtful. The literature on this subject is extremely vague. First, skin tests with human serum, which have been carried out occasionally in cases of transfusion rashes to support the allergic theory, usually lack the necessary controls. Secondly, only single cases of transfusion rashes have been reported, and no experiments on a larger scale are found in the literature. Thirdly, hardly any evidence has been published regarding the changes of reaction towards increased or reduced sensitivity after serum transfusions. The results of the present investigations throw some light on the following points.

1. **Local reactions** caused by intradermal injections of serum are indistinguishable in their features of wheal and erythema from those occurring after tests with the known atopens. It seemed plausible, therefore, that this reaction could be looked upon as evidence of allergic sensitiveness, but it had to be kept in mind that not all urticarial reactions are manifestations of allergy. The visible reactions to many substances like histamine, peptone, atopens, and serum are extraordinarily similar. Their relation lies in the common point of attack—the capillary wall. In their mechanism they differ profoundly. Histamine and peptone, as representatives of one group, act directly on the capillary wall. They act in any person. The atopens, on the other hand, produce vasodilatation indirectly as a sequel to their union with their reagins. Thus they react only in sensitized tissues. The present investigations produced evidence in favour of the assumption that local serum reactions are an atopic manifestation. It was shown that positive serum reactions were seldom obtained in normal subjects, but frequently in those individuals who gave positive reactions to the known atopens.

2. The general urticarial reactions following serum transfusion are related, in the similarity of the clinical features, to the condition caused by intravenous injections of atopens—e.g., pollen. The onset of the rash is sudden and the duration short. It may be accompanied by rhinitis, bronchial asthma, severe headaches, intestinal spasms, and fall of blood pressure. The same considerations, however, as discussed for the local reaction hold true for the general eruption. Not all attacks of urticaria, asthma, etc., are manifestations of atopy, and the clinical features alone are therefore not sufficient evidence for the atopic aetiology of the transfusion rashes. It was shown by this study that the serum rashes after transfusions most probably constitute atopic phenomena, as they were not observed in the normal controls, but only in the known atopic subjects.

Thus it seems likely that the atopic sensitiveness of the recipient is the cause of these serum reactions, and it is

surprising that the majority of case reports in the literature refer only to the allergic donor (*Lancet* editorial, 1941). Although the role of the allergic recipient is mentioned sometimes in discussions on allergic transfusion reactions (Polayes and Lederer, 1932, Kilduffe and De Bakey, 1942) only one case report of an allergic recipient developing a transfusion rash was found in the literature (Stewart and Bates, 1938). Bottner (1924), Brem *et al* (1928), and Price (1934), considering the sensitiveness of the recipient as the cause of transfusion reactions, do not refer to urticaria and related syndromes, but to febrile reactions. Duke and Stofer (1924), who are also frequently quoted as having observed an allergic reaction in a sensitive subject after transfusion, do not describe a typical allergic syndrome, but a coma.

Nothing is known of the character or source of the atopic substances in human serum. The fact is notable that fresh autoserum failed to react even in highly serum sensitive subjects, and positive skin reactions were observed only with isosera or with serum from pools. The same observation was made by Chant and Gay (1927) in a fairly large series of cases. This may indicate that the reacting substances are foreign to the human body. Furthermore, it is interesting that a serum-sensitive person does not respond equally strongly to different human sera.

Levine and State (1942) claim that the soluble A and B substances produce the positive serum reaction and the serum rashes. No confirmation of their observations has yet been published. Nor was it obtained by the results of the present skin tests with A and B sera.

There is some reason to believe that the presence of extraneous atopens—e.g., food or inhalants—in the transfused serum may be the cause of the serum reactions in sensitive subjects. In this respect Walzer's and Freeman's researches are noteworthy. Walzer (1927) sensitized small areas of normal skin passively with serum from persons who were highly food-sensitive. When the normal recipients, on the following day, ate the corresponding food, the sensitized site responded promptly by producing a wheal and an erythema. This proved the absorption of food atopens from the non-allergic digestive tract. The absorption of pollen atopen from the non-allergic mucous membrane of the nose was shown by Freeman (1925) in a similar way.

3. Desensitization—In the present series 10 out of 11 serum sensitive subjects, after recovery from a transfusion rash, showed a condition of desensitization on re-transfusion. Thus, on repetition, the administration of serum caused no urticaria or only the slightest rashes in subjects who had reacted previously. The reaction to the first serum transfusion cannot be due to nervous excitement, as several cases had preliminary saline transfusions without reaction. The refractoriness may only be temporary. It was, however, still present in several cases transfused three months after desensitization had been established. The refractory state of transfused atopic subjects resembles the desensitization in anaphylaxis, since sensitive animals surviving a sufficiently strong dose of their antigen do not react to a second dose of the same antigen. That the desensitizing effect can also be produced by whole blood was shown by Young (1942). She investigated the reactions of three subjects who responded with a transfusion rash when receiving blood for the first time. When blood of another donor was used for repetition of the transfusion a rash developed again. On the other hand, when using the same donor's blood for a second time no reaction occurred. Apart from these cases no definite reports on desensitization by transfusion could be found in the literature. Concurrently with the change of reaction to serum there occurred in bronchial asthmatics a marked improvement of the general condition and a decrease of or even a freedom from asthmatic attacks. This may be due to immunological changes. On the other hand, it may be due entirely to psychological factors, as it cannot be denied that transfusion with "normal serum" means in practice for every patient some psychological impression.

Summary

Pooled human serum, dried and then reconstituted, when used for skin tests gave positive reactions in 77% of atopic subjects, but in only 20% of non-atopic. Sera from single individuals also gave

positive reactions in the same recipient. Autoserum failed to react. The skin reacting properties of serum were independent of the group specific substances.

On transfusion, such serum caused "allergic" reactions in 14 out of 17 atopic recipients, but in none of the 21 non-atopic.

On repeated transfusion in 14 atopic and in 14 non atopic cases no sensitization occurred.

On repeated transfusion, desensitization was observed in 10 out of 11 serum sensitive atopic cases.

In the course of the follow up of patients who received serum transfusions a number of cases of homologous serum jaundice were observed. In some of the cases the hepatitis was mild (Loutit *et al*, 1944), in others as yet unreported acute hepatic necrosis occurred. Further attempts at desensitization of allergic patients with human serum, therefore, are not at present advised in this country.

I wish to thank Dr. A. N. Drury for suggesting this line of research and Dr. J. L. Livingstone and other members of the E.M.S. medical staff of Sections 8 and 9 for their co-operation in investigations of patients under their care. I am especially indebted to Dr. J. Loutit, Director of the S.W. London Blood Supply Depot, for his great help and interest at every stage of this study.

INCIDENCE OF BLEEDING GUMS AMONG R.A.F. PERSONNEL AND THE VALUE OF ASCORBIC ACID IN TREATMENT

BY

W. P. STAMM, MB, B.S.

Wing Commander

T. F. MACRAE, D.Sc., Ph.D.

Wing Commander

AND

SIMON YUDKIN, Ph.D., M.B., M.R.C.P.

Flight Lieutenant

(R.A.F. Institute of Pathology and Tropical Medicine)

Reports appearing in medical journals recording good results obtained by the treatment of various forms of gingivitis with ascorbic acid led to a very large consumption of that substance in the Royal Air Force for the treatment of all forms of bleeding gums. An investigation was therefore carried out between October, 1941, and May, 1942, to discover the incidence of bleeding gums in the R.A.F. and to assess the value of ascorbic acid in the treatment of this condition.

Experiment 1

This experiment took place at three R.A.F. stations during October and November, 1941. At each station all personnel available were examined, except those already taking ascorbic acid, those being treated for acute ulcerative gingivitis stomatitis and those with no teeth. About two-thirds of those examined were airmen, the remainder were airwomen and soldiers, with a few officers, sergeants, and naval personnel. The majority of subjects in this and later experiments were between the ages of 18 and 25. All those included in this experiment had been living on Service rations for six months or more. An estimation was made of the ascorbic acid content of the airmen's food during the experimental period and in the early spring of 1942.

Methods

The gums of the lower jaw were examined for bleeding after digital massage. Three degrees of bleeding were recognized and noted: (a) bleeding just perceptible at one or two points after firm massage; (b) bleeding more easily produced or bleeding from several points; (c) bleeding apparent on inspection or at the slightest touch. Where gums showed bleeding, ulceration and redness were also looked for, being classified as "absent," "present," or "marked."

Alternate members of the group with bleeding gums were given ascorbic acid tablets and dummy tablets flavoured with tartaric acid. The dose of ascorbic acid was 200 mg. daily for 7 days, followed by 100 mg. daily for 14 days; the dummy tablets were similar in appearance and taste, and were given in similar numbers. Distribution of the tablets was conducted under the supervision of section N.C.O.s, to whom each man had to report daily. The tablets had to be chewed and swallowed in the presence of the N.C.O.s, who kept records of attendances. The dental officer at each station was supplied with a list of those in the experimental group and was asked not to carry out any dental treatment on them during the period of the test.

At the end of the experimental period of three weeks all subjects given ascorbic acid and dummy tablets were re-examined. The original notes were not available to the examiner, so that he could not be influenced by his previous observations or by a knowledge of which tablets had been given. After examination each individual was asked whether he had noticed any improvement or deterioration during treatment. For various reasons not connected with the experiment about 27% of the subjects were not available at the second examination.

The ascorbic acid content of the food as served to the airmen in the messes was determined by the dichlorophenol-indophenol technique (Harris and Oliver, 1942) during one week of the experimental period at each station. The average weight of each item consumed by the personnel in their messes at each of the 28 meals served during the week and the ascorbic acid content per unit weight of each of these items at the time of serving were determined. The average intake of ascorbic acid per airman at each station was calculated from these data. This determination of the ascorbic acid intake was repeated at the same stations in March, 1942, in order to discover the degree of seasonal variation.

Results

The total number of personnel examined at the three stations was 1,791, and 344 of these had some degree of bleeding of the gums—a percentage of 19.2. The incidence varied between the stations and between different classes at the same station, but not to any significant extent (Table I).

TABLE I.—Incidence of Bleeding Gums at the Various Stations and in the Different Classes of Personnel. (Experiment 1)

Station	Number Examined	Number with Bleeding Gums	Percentage with Bleeding Gums
1	521	101	19.4
2	708	111	15.7
3	562	132	23.5
Total	1,791	344	19.2

Class of Personnel	Number Examined	Number with Bleeding Gums	Percentage with Bleeding Gums
Airmen	1,191	215	18.0
Airwomen	271	57	21.0
Sergeants	68	22	32.4
Officers	10	3	30.0
Army	215	45	20.9
Navy	36	2	5.5
Total	1,791	344	19.2

Of those with bleeding gums 250 completed the test—119 receiving ascorbic acid and 131 dummy tablets. Table II summarizes the effects of the two treatments on the bleeding, ulceration, and redness of the gums. There was no significant difference between the effects

TABLE II.—Effect of Treatment with Ascorbic Acid on Bleeding, Ulceration, and Redness of Gums. (Experiment 1)

	Treated with Ascorbic Acid				Treated with Dummy Tablets			
	Im- proved	No Change	Deterior- ated	Total	Im- proved	No Change	Deterior- ated	Total
Showing No bleeding %	43	61	15	119	53	64	14	131
No. showing ulceration	36	51	13	40	5	49	10.5	25
No. showing redness	3	19	1	23	10	14	1	25
	36	42	8	86	51	33	8	92

produced by ascorbic acid and by the control tablets; the apparent better effect of the latter tablets was probably due to chance.

Ulceration developed during the experiment in 5 of the 119 treated with ascorbic acid and in 9 of the 131 given dummy tablets; redness developed in 6 of the ascorbic acid group and in 9 of those receiving dummy tablets. The effects of the treatments were worked out for each station and for each class of personnel, but as the results showed no significant difference the details have been omitted. Subjective feelings of improvement usually bore no relation to the objective signs, but when there was any marked change in the degree of bleeding this had usually been noticed when the teeth were being cleaned.

The results of the estimations of ascorbic acid intake are summarized in Table III. The average daily intake of the airmen was about 26 mg. each during the autumn and 17 mg. during the early spring.

TABLE III.—Average Daily Intake of Ascorbic Acid by Airmen in their Messes at Three R.A.F. Stations. (Experiment 1)

Station	First Series of Tests (Autumn)		Second Series of Tests (Spring)	
	Test Period	Ascorbic Acid Intake (mg. per man daily)	Test Period	Ascorbic Acid Intake (mg. per man daily)
1	8/10/41 to 15/10/41	25.5	3/3/42 to 9/3/42	19.0
2	21/10/41 to 28/10/41	27.0	11/3/42 to 17/3/42	15.2
3	5/11/41 to 12/11/41	24.8	19/3/42 to 25/3/42	16.3
Average:		25.8		16.8

The main cause of the difference between the ascorbic acid intake in the autumn and that in the spring was the ascorbic acid content of the potatoes. Potatoes contributed an average of about 11 mg. of ascorbic acid per man daily in the autumn, but only about 6 mg. in the spring. Potatoes were the most important source of ascorbic acid in the autumn, but in early spring greenstuffs provided the largest amount. Taking the two test periods together, potatoes and greenstuffs contributed about equal amounts, and between them supplied about three-quarters of the total ascorbic acid, the remainder being derived from root vegetables, the small amounts of fruit served, jam, and a number of less important sources.

Experiment 2

At another R.A.F. station 571 airmen were examined and treated for bleeding gums during April, 1942. The same methods were used as in experiment 1, except that special note was made of the presence of "sponginess" of the gums and that the dosage of ascorbic acid was slightly different. In this second experiment 150 mg. was administered daily for 20 days. The dietary history of the personnel of this station differed from that of the personnel of experiment 1, as the men had received Service rations for periods of only one to six weeks before the beginning of the experiment; previously they had lived in civilian billets and received civilian rations.

Results

The number with bleeding gums was 122—an incidence of 21.3%. The effects of the treatments on all cases of bleeding gums are given in Tables IV and V. Those with and without "sponginess" of the gums have been separated into two groups, and the effects of the two treatments have been worked out for each group. Six of those with bleeding gums failed to complete the experiment.

TABLE IV.—Effect of Treatment with Ascorbic Acid on Bleeding Gums. (Experiment 2)

Treatment	Improved		No Change		Deteriorated		Total
	No.	%	No.	%	No.	%	
Ascorbic acid	17	25	37	54	14	21	68
Dummy tablets	22	46	14	29	12	25	48

TABLE V.—Comparison of Effects of Treatment on Bleeding Gums with and without "Sponginess." (Experiment 2)

Treatment	"Sponginess" Present					"Sponginess" Absent				
	Improved		Deteriorated or no Change		Total	Improved		Deteriorated or no Change		Total
	No.	%	No.	%		No.	%	No.	%	
Ascorbic acid	9	33	18	67	27	18	44	23	56	41
Dummy tablets	8	47	9	53	17	23	74	8	26	31

Again the dummy tablets were rather more effective than the ascorbic acid, but the difference was not statistically significant. Improvement was shown by a significantly larger proportion of those having no "sponginess" compared with those with "sponginess" present, but the better results were independent of the form of treatment.

Experiment 3

This experiment was carried out during April and May, 1942, at the same station as experiment 2, as part of a more general nutritional survey. Six hundred airmen, other than those taking part in experiment 2, were examined three times at intervals of three weeks, and at each examination the presence or absence of bleeding gums was noted. After the initial examination the men were divided into several groups which were given different vitamin supplements and control tablets.

Results

The incidence of bleeding gums on initial examination was 20.3%—a figure similar to those found in the two previous experiments. The results of treatment with ascorbic acid and other vitamin supplements showed no significant difference. It therefore seems justifiable to consider the observations made on the 600 airmen as a whole.

There was almost exactly the same percentage showing bleeding gums at each examination, and the distribution of the degrees of bleeding was similar on each occasion (Table VI). On the other hand, only 57 of the 122 who showed bleeding at the initial examination did so at each of the two subsequent examinations.

TABLE VI—Number with Bleeding Gums at Three Examinations of 600 Airmen at Intervals of Three Weeks (Experiment 3)

	Degree of Bleeding*			Total	
	a	b	c	Number	% of 600
1st examination	43	50	19	122	20.3
2nd "	42	53	16	111	18.5
3rd "	52	53	13	118	19.7

* The degrees are defined in the account of experiment 1.

At the second examination the gums of 48 subjects (19% of the original 122) had stopped bleeding entirely—about the same percentage as showed improvements in experiments 1 and 2—but at the same time 37 of the rest of the 600 had started to bleed. Similarly, at the third examination 34 had stopped bleeding, while 41 had started. It is thus apparent that there is a considerable normal variation irrespective of treatment.

It was observed in this experiment, as in experiment 2, that those gums with "sponginess" tended to remain unchanged from one examination to the next. The majority of those who showed improvement during the test period had fairly firm, pale gums with only a little bleeding on massage. Neither type showed greater improvement with any particular treatment.

Discussion

In frank scurvy, swollen spongy bleeding gums are a characteristic sign. Most investigators who have treated bleeding gums with ascorbic acid have reported improvement in at least a portion of those affected, and have inferred that bleeding gums may be an early sign of ascorbic acid deficiency (Roff and Glazebrook, 1939; Campbell and Cook, 1941, 1942; Blockley and Baenziger, 1942; Stuhl, 1943; Kent, 1943).

There is no evidence from the early descriptions of scurvy (Hakluyt, 1600; Lind, 1753) that the gums began to bleed before the other signs and symptoms were seen, and during the investigations on experimental human scurvy by Crandon, Lund, and Dill (1940) the gums did not become swollen and haemorrhagic before other signs of scurvy appeared. Work by Burrill (1942) showed no relationship between low blood plasma vitamin C levels and the presence of gingivitis, and McNece and Reid (1942) found patients with sore bleeding gums to be no more "unsaturated" than others.

In the present experiments estimation of the intake of ascorbic acid showed that even in the autumn, when it might be expected to be high, the amount in the food served to the airmen on three R.A.F. stations was about 25 mg daily, or slightly less than the amount considered desirable by the Health Organization of the League of Nations (30 mg daily). The ascorbic acid intake during the spring was little more than half that recommended. Subsequent experiments on other stations have

confirmed that the average between these spring and autumn figures is representative of the average figures throughout the year on most R.A.F. stations. It might reasonably be expected, therefore, that if gingivitis were an early sign of ascorbic acid deficiency a noticeable proportion of those with bleeding gums would have shown improvement with ascorbic acid treatment.

In all three experiments the gums of those treated with ascorbic acid showed no greater improvement than those of the control groups, and the incidence of bleeding gums was remarkably constant (about 20%), although the subjects of experiments 2 and 3 had been living on civilian rations in billets until a short time before those experiments. The opinions of patients as to the efficacy of the treatments were found to bear no relation to the objective signs. Those gums which were not "spongy" tended to improve more than those with "sponginess," but the improvement was irrespective of the type of treatment.

Observation of 600 subjects in whom there was a 20.3% incidence of bleeding gums at the first examination showed that there is a large normal variation in the condition of gums, although the total incidence of bleeding gums remains very constant. This may well be the explanation of the apparent success in treatment with ascorbic acid which has been so often reported.

It seems justifiable to conclude that in Royal Air Force personnel in this country ascorbic acid is valueless in the treatment of bleeding gums, and the incidence of bleeding gums is not related to the ascorbic acid intake. This does not exclude the possibility that other subjects living under different dietary conditions might benefit from treatment with ascorbic acid.

Summary

The average amount of ascorbic acid present in the food served to airmen at three R.A.F. stations was 25.8 mg per man daily during October and November, 1941, and 16.8 mg during March, 1942.

On examination of 2,962 personnel, 588 (19.8%) were found to have some degree of bleeding of the gums, a similar incidence being found in the autumn and spring and at each of the four stations where the investigations were carried out.

No greater improvement in the gum conditions was obtained by treatment with ascorbic acid than with dummy control tablets.

Observation of 600 personnel over a six weeks period showed that there was a large normal variation in the degree of bleeding of the gums, irrespective of treatment.

Those having "sponginess" as well as bleeding of the gums showed no greater improvement with ascorbic acid treatment than with dummy tablets, although there was less normal variation in their condition.

Patients' personal opinions as to the efficacy of treatment bore no relation to the objective signs.

We are indebted to Dr Bradford Hill for the statistical analysis of the results, and wish to thank the officers, airmen, and other personnel at the stations where the experiments were carried out for their co-operation.

Several English cities are likely to benefit from Mr William Eichholz's £100,000 legacy for the development of the Alfred Eichholz Memorial Clinic in London and of the blind professional masseur generally. The National Institute for the Blind, which administers the clinic, hopes to use some of the money to open similar clinics in provincial centres. When the Institute founded the Eichholz Clinic in 1931 Mr Eichholz paid all the cost of its establishment and equipment as a memorial to his late cousin, Dr Alfred Eichholz of the Board of Education. He became an enthusiastic admirer of the ability of his blind staff. All the new clinics in the Provinces will be staffed by blind physiotherapists trained at the Institute's school. This was enlarged last year to meet the training needs of war casualties in the Forces and among civilians.

INCIDENCE OF GINGIVITIS IN THE ROYAL AIR FORCE

BY

G. A. SMART, M.D., B.Sc., M.R.C.P.

Squadron Leader, R.A.F.V.R.

(R.A.F. Institute of Pathology and Tropical Medicine)

In the course of an inquiry into gingivitis in the Royal Air Force, initiated by Air Marshal Sir H. E. Whittingham, Director-General of Medical Services, the incidence of this condition was determined at four Royal Air Force stations.

Classification

Since the various forms of gingivitis are not clearly defined, it was decided to adopt a classification which would avoid ambiguity and which was based on naked-eye appearances. The gums of those examined were assigned to one or other of the following categories.

A. Normal.

B. Gingivitis without Ulceration.—In this group the gums and the interdental papillae are swollen, bluish red in colour, frequently bleed on pressure, and, adjacent to the teeth, may have a smooth shiny appearance with absence of the normal stippling. Such gums are often sensitive when touched with a probe. The lesion most frequently occurs in the region of the lower incisors. When viewed through the corneal microscope the normal cornified layer may be seen to stop short about 2 to 3 mm. from the crest of the gum. Between this point and the crest the gum is swollen and oedematous, and the capillaries lie in long loops, like hairpins, whereas in the normal gum, and in the region where the cornified layer is still present, they are convoluted. Purely local patches of hyperaemia due to obvious trauma or to toothbrush abrasions were not regarded as this type of gingivitis.

C. Healed Gingivitis.—The interdental papillae are missing and the gums are pale, but thickened and rolled in appearance. There is no evidence of existing inflammation; it is clearly a healed condition. Those who have suffered previously from gingivitis and have undergone treatment often have gums of this type.

D. Chronic Ulcerative Gingivitis.—Cases in this group usually resemble Type B gingivitis with a superadded chronic ulceration, frequently at the tip of one or more interdental papillae. The ulceration may occur more deeply, between the gums and the necks of the teeth; the appearance is then of an early periodontitis.

E. Acute Ulcero-membranous Gingivitis and Gingivostomatitis.—This can be subdivided into two groups: (i) arising on apparently healthy gums; (ii) arising on gums which show evidence of pre-existing inflammation. Types E i and E ii constitute the entity known as trench mouth, and often the presenting symptom is pain. This can be of two varieties: (a) pain of an aching character, localized to the region of the affected gum—throbbing may occur if the lesion is acute; (b) dull aching pain, like toothache, situated deeply and not well localized. Foetor oris is always present, and, contrary to some teaching, may be noted by the patient. Bleeding of the gums usually occurs with mild trauma, as from tooth brushing, but it can arise spontaneously, and may be the presenting symptom. The lymph glands which drain the affected area may be swollen and painful. The lips are often crusted, the lower lip and the angles of the mouth being most frequently affected. The tongue may be swollen and show marginal indentations from pressure of the teeth. The gums are swollen, hyperaemic, and turgid in appearance; the normal line of demarcation between the pale mucous membrane of the gum and the redder mucous membrane of the gingivo-labial fold is absent.

Two types of ulceration may be present, concurrently or separately. In the more acute form a narrow serpiginous band of ulceration, with apparent membrane formation, extends round the necks of the teeth; it is confined to the region of the alveolar crest. This process may stop abruptly if a gap due to previous dental extractions exists between the teeth. Rarely, ulceration occurs on that part of the buccal mucous membrane in contact with the affected gum. Ulceration may also occasionally extend on to the mucous membrane of the fauces and soft palate. The other type of ulceration does not seem to be so acute, and it is confined to the tips of some of the interdental papillae. Both types of ulceration occur about the incisor teeth, but the lesions may be generalized or they may be confined to other regions of the mouth.

The chief general disturbances are lassitude and mental depression, but these may be entirely absent. The temperature is usually normal, but it may be slightly raised. There is no characteristic blood picture, but occasionally a slight polymorphonuclear leucocytosis may occur.

Method of Investigation

At each of the stations concerned a random sample of the personnel was taken from the nominal roll. These were ordered to attend for examination. If, owing to leave, sickness, or other cause, any of those selected could not be present, the reason was stated by the section concerned. At the first station to be examined the random sampling was carried out by Dr. Bradford Hill. Each subject, when examined, was required to give details of age, sex, Royal Air Force or Women's Auxiliary Air Force trade, civilian occupation before joining the Service, and date of joining. The gums were then classified into one or other of the above groups.

Results

Tables I to IV show the incidence of the various types of gingivitis at the four R.A.F. stations.

TABLE I.—Incidence of Gum Lesions among Personnel at
Fighter Station I

% ..	67.9	32.1	62.1	37.9	45.9	54.1	36.3	63.7

Table VI shows the proportions of the various types of gingivitis at the four stations where the survey was carried out. About 75% of all subjects with gingivitis have a Type B lesion. A chronic ulcerative gingivitis is present in about 15%, but the proportion varies greatly at different stations. That at Fighter Station I is significantly higher than the proportion at Fighter Station II or at Bomber Station IV. This is chiefly due to variations in the numbers of older personnel examined at each of the stations. Only 3 subjects suffering from acute ulceromembranous gingivitis were found.

In subsequent analyses all types of gingivitis have been grouped, since the numbers of all but Type B are too small to be subdivided, and since most authorities agree that in a large proportion of cases chronic ulcerative gingivitis (Type D) is an extension of Type B.

TABLE VI.—Proportions of Various Types of Gingivitis at Four R.A.F. Stations

Station	Type of Gingivitis						Total
	B	C	D	E i	E ii		
Fighter I ..	56 (65.8)	7 (8.2)	22 (26.0)	0	0		85 (100)
II ..	50 (89.0)	10 (10.0)	9 (9.9)	0	1 (1.0)		100 (100)
Bomber III ..	114 (73.2)	14 (9.0)	26 (16.7)	0	2 (0.1)		156 (100)
IV ..	91 (82.0)	9 (8.1)	11 (9.9)	0	0		111 (100)
Total ..	341 (75.4)	40 (8.9)	68 (15.0)	0	3 (0.7)		452 (100)

Figures in parentheses represent percentages.

The social status of 540 airmen taken at random from those examined was arrived at from their pre-Service civilian occupation (Medical Research Council, 1944), and the percentage of those with normal gums (edentulous subjects excluded) in each social grade was determined. Table VII shows these results.

TABLE VII.—Gingivitis and Pre-Service Social Status

Gums	Social Class					Total
	1	2	3	4	5	
Normal	7	62	203	35	11	315
Gingivitis ..	2	33	136	43	11	225
Total ..	9	95	336	78	22	540
%, Normal	77.7	65.3	59.5	44.9	50.0	—

The incidence of gingivitis of all types (edentulous subjects excluded) in the different R.A.F. trades is shown in Table VIII. The figures therein have been corrected for age differences in the following manner. The age distribution of the whole of the population was first determined, and this was taken as a standard (Table IX). The incidence of gingivitis among those susceptible in each age group of each trade was then found, and was applied to the respective age group of the standard population. The results in each trade were added, the figures shown in Table VIII being obtained. This correction was necessary because of the vastly different age distribution in different trades and because of the relation of the incidence of gingivitis to age, which can be seen in Table V.

TABLE VIII.—Gingivitis in R.A.F. Trades, corrected for Age Differences. (Edentulous Personnel excluded)

Trade	% Gingivitis
Air-crew	22
Cooks, butchers, batmen, waitresses	60
Group I trades	34
II ..	45
III ..	40
IV ..	44
V ..	44

Cooks and butchers, batmen, and waitresses have been excluded from their respective trade groups. Too few personnel in Group III and "M" were examined for an adequate comparison to be made. In general, Group I contains the more skilful and more highly paid workers.

TABLE IX.—The Age Distribution of the Standard Population. (This was obtained from the Average Age Distribution of all Four Stations)

Age Group	No. of Persons
-25	52.7
26-30	17.0
31-35	17.4
36+	12.9
	100.0

Table X shows the incidence of gingivitis among susceptible subjects grouped according to length of service. These figures have been corrected for differences in age distribution in the same way as those obtained for the various R.A.F. and W.A.A.F. trades.

TABLE X.—Incidence of Gingivitis, corrected for Age, according to Length of Service in the R.A.F. (Edentulous Personnel excluded)

Length of Service (mths.)	No. Examined	% Gingivitis
0-11 ..	122	41.14
12-23 ..	160	35.82
24-35 ..	275	40.22
36+ ..	152	36.11

Discussion

Sex Incidence.—Tables I, II, III, and IV show that only at Bomber Station IV was the incidence of gingivitis among airwomen different from that among airmen of the same age group. At this station the difference is statistically significant ($P=0.03$), the airwomen being worse. Furthermore, the incidence among airwomen at this station is just significantly higher than that among those at the other three stations ($P=0.05$). The reason for these differences is not known, but it would seem that there is usually no difference in the incidence of gingivitis among the two sexes.

Age Incidence.—Table V shows clearly that the incidence of gingivitis is greater in the older age groups. It is necessary, therefore, to apply a correction for age distribution when the incidences of gingivitis in two different groups are to be compared. The method of carrying out this correction has already been described; it has been applied to the different stations examined, and the corrected incidence of gingivitis so found is shown in Table XI.

TABLE XI.—Incidence of Gingivitis in the Susceptible Population of Each of Four R.A.F. Stations, Corrected for Age to the Standard Population

Station	% Gingivitis
I ..	43.6
II ..	42.4
III ..	40.0
IV ..	39.9

Incidence compared with Other Groups.—It is difficult to compare the incidence of gingivitis found in the R.A.F. with that found by other investigators among other groups of subjects, since the standards of diagnosis are so variable. During the last war Semple, Price-Jones, and Digby (1919) found that 29.5% of one unit had gingivitis. Whittingham (1932), during an extensive investigation into the aetiology of tonsillitis, examined the gums of nearly 3,000 R.A.F. and Army apprentices between the ages of 16 and 19. Table XII shows the results he obtained.

TABLE XII

R.A.F.	No. Examined	% Gingivitis
Army	2,085	16.9
	655	34.4

Considering the difference in age, it is seen that the incidence found in R.A.F. apprentices is similar to that found in the present investigation for air-crew, while the incidence for Army apprentices is similar to that for other R.A.F. trades. The boys who became aircraft apprentices in 1930 were of much the same social class as those now volunteering for air-crew duties, whereas people who became Army apprentices were similar to those who now enter the other R.A.F. trades. More recently Roff and Glazebrook (1940) found the incidence in naval trainees to be 17.6%. This figure again is close to that obtained in the R.A.F. apprentices, and it is probable that both groups were recruited from similar sections of the population.

MacDonald (1943) examined 614 naval personnel and found the incidence of gingivitis to be 28.5%. In this figure, however, no correction has been made for age (although the author shows

that there is an increase in the incidence of gingivitis with increase in age, and edentulous subjects—who, as he points out, are not susceptible—are included in the total. Exclusion of the latter brings the incidence to 30.5%, but this figure is uncorrected for age. For those under 30 years the incidence was 17.7%. In the present investigation the incidence of gingivitis among airmen and airwomen under 30 years (including edentulous subjects for the sake of comparison) was found to be 32.7%. The age-corrected incidence of gingivitis among those susceptible in the R.A.F. is approximately 40%.

Influence of Social Status.—The figures in Table VII show that there is a correlation between the incidence of gingivitis and pre-Service social status, the condition being less prevalent in the higher-income groups. It is beyond the scope of this paper to discuss the reason for this, but both dietetic factors and differences in personal hygiene may be involved.

Incidence in Various R.A.F. Trades.—The incidence of gingivitis among air-crews is significantly less than that among the rest of the R.A.F., due correction having been made for age differences; but it should be noted that only specially selected air-crew personnel were posted to the stations which were examined. On the other hand, the incidence among those engaged in messing and in the preparation of food is significantly higher than among the remainder, excluding air-crew. If the condition is infectious this finding is obviously important.

Whether the differences in the incidence of gingivitis among personnel engaged in the different R.A.F. trades are due to specific working conditions it is difficult to say; but the fact that different trades recruit their members in different proportions from the various social classes must certainly play a large part in producing the variations which have been found. This supposition is supported by the fact that there seems to be no relation between the incidence of gingivitis and length of service in the Royal Air Force.

Summary

A survey of the gums of random samples of airmen and airwomen from each of four Royal Air Force stations has been carried out.

The incidence of gingivitis was approximately 40%. It was higher among those susceptible in the older age groups and in those recruited from the poorer social classes. Length of service in the R.A.F. did not seem to influence the incidence of gingivitis. Significant differences were found among the various trade groups, the incidence being lower among those who were more highly paid.

The reasons for these differences have been discussed.

Thanks are here recorded to Air Marshal Sir H. E. Whittingham, who initiated the investigation and who allowed the extensive facilities necessary for carrying it out; to Air Commodore T. McClurkin, Director of Hygiene, for his help and encouragement; to Dr. Bradford Hill, for advice concerning the sampling and for his assistance in the analysis of the results; and to Dr. B. S. Platt for much information, help, and encouragement. Thanks are also recorded to the commanding officers, medical officers, and dental officers who were concerned in the organization of the experiments.

RUPTURE OF AORTIC ANEURYSM INTO THE DUODENUM

BY

J. EDGAR MORISON, M.D., B.Sc.

Lecturer in Morbid Anatomy, Queen's University; Pathologist, Belfast City Hospital

One of the rarest causes of fatal intestinal haemorrhage is rupture of an aortic aneurysm into the gut. Howland and Sprockin (1943) reported a case and found 4 similar cases recorded since 1936, when Kampmeier (1936) discovered 9 cases in the literature and contributed another. These 15 cases are included in their summary of 520 cases of abdominal aneurysm recorded up to Dec., 1942. Four aneurysms of the abdominal aorta—two rupturing into the retroperitoneal tissues, one into the duodenum, and a small asymptomatic one—have

been seen. The present case of haemorrhage into the duodenum is worthy of record, and the diagnosis was suggested before necropsy.

Clinical History

The patient, a housewife aged 64, complained of aching referred to both sides of the abdomen and of frequency and scalding on micturition. These symptoms, of two to three months' duration, were not incapacitating. On examination a mass the size of a cricket ball was felt to the left of the umbilicus. This was slightly fluctuant and somewhat tender, and pulsated with the heart-beat. Special examinations failed to contribute further to the diagnosis, especially as between a pancreatic cyst and an abdominal aneurysm. The urine contained *B. coli*, the blood Wassermann reaction was negative, and a fractional test meal revealed complete achlorhydria. A radiograph of the abdomen disclosed no abnormality, and with a barium meal there was no deformity of the stomach and the meal passed normally through the intestine. A urinary diastase index of 10 was normal. After rest and treatment for cystitis for three weeks the patient went home. Ten weeks later she had a very severe haematemesis and was readmitted in extreme collapse. After transfusion of three pints of blood her blood pressure rose from 60 to 85 mm. Hg systolic, but she continued to vomit blood and died in seven hours.

Pathology

Bright red blood, often in large clots, filled the greater part of the stomach and small intestine and reached to the hepatic flexure. Where its horizontal part passed into the ascending part the third part of the duodenum was lifted forwards by a globular mass adherent to its posterior aspect and to the left side of the aorta. Even after fixation this measured 6.5 by 6.5 by 4 cm. At the same level there was a vertical tear with dark red and slightly everted edges in the mucosa of the posterior duodenal wall measuring 1.5 by 0.5 cm. and communicating with the aorta through the cavity of the globular mass. This was filled with blood-clot, some of which was old and laminated, though little of it was organized. The walls were in few places more than 0.5 cm. in thickness, but there was considerable fibrosis in the surrounding retroperitoneal tissue. The entrance to this sac from the aorta was round and 1.5 cm. in diameter, while the wall of the aorta up to the very margins of the defect appeared free from stretching or scarring. The orifice of the inferior mesenteric artery was carried into the lower margin of the entrance of the sac, but its lumen contained no thrombus. The renal arteries lay above the sac and were not involved. From about an inch above the aneurysmal sac to its iliac bifurcation the intima of the aorta showed confluent hyaline plaques containing very little calcium and no grumous material. There was no intimal scarring in the region of the arch, nor adventitial thickening.

Numerous sections of the aorta showed only a little adventitial thickening and a very occasional infiltration by mononuclear cells around the vasa vasorum. The elastica of the media, even at the edge of the aneurysm, was not demonstrably altered by the fibrosed atheromatous plaques. Near the margin of the aneurysmal defect the adventitial fibrous tissue increased, and distinctive infiltrations of mononuclear cells, including plasma cells, occurred around thickened vasa vasorum and extended inwards into the media. In the disorganized wall opening into the aneurysmal sac itself the changes were less specific, plasma cells were numerous, but proliferating fibrous-tissue elements and large mononuclear cells, some containing haemosiderin, were also present, and elastic elements had almost entirely disappeared.

Complete routine histology from all organs revealed nothing of further interest apart from portal cirrhosis which was not actively progressive; the absence of the lesions of Banti's disease from the spleen, and the non-specific nature of bilateral apical lung scars.

Probably almost all these aneurysms are due to syphilis. Specific changes may be limited to small areas of the aorta, and only after very detailed study can atheroma, acute bacterial aortitis without focus elsewhere (Rappaport, 1926), or aortitis of undetermined origin (Sprout and Hawthorne, 1937) be considered. Atheroma was not unusual or excessive in the present case. The plaques were largely fibrosed, and, while the changes in the wall at the actual site of the aneurysm cannot now be known, it is reasonable to believe that the mural defect was secondary to changes in the vasa vasorum similar to those noted in the thickened adventitia and in the media at the margin of the aneurysm. Syphilitic aortitis is often the cause of an aneurysm; atheroma is much more common, and yet it is difficult to obtain evidence that it is ever responsible.

In 900 necropsies on patients over 30 years of age with complete histology of all organs, 15 thoracic and 4 abdominal aneurysms were found to be due to syphilis and only 3 were dissecting aneurysms secondary to medial necrosis. In the same material a further 29 cases showed changes which justified

diagnosis of syphilitic aortitis. These changes were infiltrations by a few plasma cells around the vasa vasorum and often a little adventitial fibrosis. This gives an incidence in our material of 2.1%, for syphilitic aortic aneurysm, and 5.3% for syphilitic aortitis. These figures would be approximately halved if all necropsies at all ages and those limited to the cranium were included. An incidence of 1.7% and 2.7% is given by Bryant (1903) and by Osler (1905) respectively for aortic aneurysm, but reviews of the subject ignore the age composition of the necropsy material. The negative Wassermann in the present case need occasion no surprise for in just over half the recorded cases the reaction was negative.

Summary

In 900 complete necropsies on patients over the age of 30, 15 thoracic and 4 abdominal syphilitic aneurysms and 29 cases of syphilitic aortitis were found. A case of rupture of an abdominal aneurysm into the duodenum is reported.

I wish to thank Dr F. M. B. Allen for clinical notes on this case.

Medical Memoranda

Rupture of Rectus Abdominis as a Complication of Pregnancy

A paper by Mr. Rufus Thomas in the *Journal* of July 31, 1943 (p. 136), and a letter from Dr. Nora Keevil published on Aug. 21, 1943 (p. 245) drew my attention to the rarity of rupture of the rectus abdominis as a complication of pregnancy. I therefore thought that it might be worth while publishing the record of a case which I treated before joining the Forces.

Mrs. A., aged 37, was admitted to hospital at 9.25 p.m. on May 14, 1941. She was a para 6, whose five previous pregnancies had ended in two premature labours (both infants alive and well) and three abortions. Present pregnancy L.M.P. Oct. 10, 1940 (31 weeks duration at time of admission). She had been well, apart from some chronic bronchitis until four hours before admission, when she was seized with a sudden pain in the upper right quadrant of the abdomen. The pain remained constant. She vomited once. There was no vaginal haemorrhage or discharge. Her doctor had sent her to hospital with a diagnosis of ? ovarian, ? fibroid, ? appendix.

When examined in hospital the uterus was found to correspond to a period of amenorrhoea. There was a hard tender mass to the right of, and separate from the uterus. It was deep to the rectus muscle, and was all above the umbilicus. T 99° P 104 R 28. Laparotomy was decided upon. Diagnosis: acute abdomen. Nature of tumour not diagnosed.

Under general anaesthesia a right paramedian incision revealed a large haematoma in the sheath of the right rectus muscle and deep to the muscle. The muscle fibres were torn opposite the tip of the ninth costal cartilage and the terminal branches of the deep epigastric were torn across. The clot was evacuated and the bleeding vessels secured. The peritoneum was opened and found normal, it was then closed. A corrugated rubber drain was put into the rectus sheath and the wound closed. Apart from some vaginal bleeding the day after operation, convalescence was uneventful. She was discharged on June 13—30 days after operation. She reported to the antenatal department on June 24, and was found to have bronchitis and albuminuria. She was readmitted to hospital and remained there till full term. She had a normal delivery of a female infant weighing 6 lb 10 oz on July 21. She was finally discharged on Aug. 1. Mother and infant were both well.

Medical and surgical self adhesive plasters now contain a proportion of synthetic rubber. Their life continues to be adequate for all reasonable requirements, but they cannot be guaranteed to withstand storage over long periods. The Medical and Surgical Plaster Makers' Conference advises dealers to rotate their stocks regularly to eliminate the possibility of goods lying on shelves. Stock which has not been turned over may deteriorate and cannot be replaced, or credited by the manufacturers.

Reviews

NUTRITIONAL DEFICIENCIES

Nutritional Deficiencies: Diagnosis and Treatment By John B. Youmans. M.D. assisted by E. White Patton M.D. Second edition (Pp. 359. Illustrated 30s.) London: J. B. Lippincott Company.

This book was written essentially for clinicians, and during the 18 months between the appearance of the first edition and the preparation of the second, little work applicable clinically has appeared. The additions to the book include the changes in the eye in vitamin A deficiency and the use of blood vitamin A determinations. The chief parts rewritten are those concerning the diagnosis of thiamine, nicotinic acid, vitamin C and other possible nutritional deficiencies. The table of the recommended allowances of calories, protein, calcium, iron, vitamins A, B₁, C, D, riboflavin and nicotinic acid of the Food and Nutrition Board of the National Research Council has been added. Though it was recognized that these were probably generous, it was also recognized that in clinical medicine a liberal factor of safety is desirable. A most valuable summary of the vitamins and the laboratory diagnosis of deficiency diseases is given at the end of the book. Section 1 gives a tabular summary of the vitamins A, B₁, nicotinic acid, riboflavin, C, D and calcium, E and K, their nature, function, dietary source, pathology, clinical expression, diagnosis, treatment, and common units of measure. Section 2 gives the principal dietary sources of the essential food factors (including the vitamins, calcium, iron, iodine, and protein). Section 3 deals fully and practically with the diagnosis of deficiency diseases by laboratory methods. The book is well printed and strongly bound.

SPANISH MEDICAL MONOGRAPHS

Diagnóstico y Tratamiento de la Epilepsia Genuina By J. J. López Ibor. Colección Española de Monografías Médicas. Barcelona 1943.

Enfermedades no Ulcerosas del Duodeno By F. Gallart Monés and E. Vidal Colomer. Colección Española de Monografías Médicas. Barcelona 1944.

These two publications are Nos. 31 and 32-3 in a series of monographs on special medical subjects under the general editorship of Dr. J. Puig Sureda. The first, by Prof. López Ibor of the Cajal Institute is a short survey of present knowledge of true epilepsy and its various manifestations. The author refers with a certain reserve to the diagnostic value of electroencephalography. Methods of treatment are briefly summarized in the last chapter. Although the author has evidently read widely in his subject and cites many other writers, no references to sources are given, and this detracts from the value of an otherwise useful and concise work. The second monograph, on non-ulcerative diseases of the duodenum, opens with discussions of anatomical and physiological considerations, radiological technique, and the normal duodenum. The following conditions are then considered: duodenitis, duodenal stenosis, chronic duodenal stasis without stenosis, periduodenitis, duodenal diverticulosis. There follow chapters on pathological anatomy, atypical placement, deformities of extrinsic origin, tumours, syphilis, and tuberculosis.

A novel feature of this series of monographs is that each one contains an appendix of signed "Practical Notes on Diagnosis and Treatment." The reviewer surmises that the main object of these is to lead the eye of the reader to the interleaved advertisements, which do not appear in the monograph itself.

ASPECTS OF INDUSTRIAL MEDICINE

Industrial Medicine: The Practitioner Handbook series (Pp. 202, 16s.) London: Eyre and Spottiswoode, 1944.

General practitioners should visit factories so as to be able to understand more clearly the working conditions of their patients, and it is for such that this book has been published. But the title is misleading: it is not a comprehensive survey of the field of industrial medicine but rather a series of essays skimming lightly with certain aspects of the problem, for which the price is rather on the high side. In an introduction Sir David Munro rightly stresses the need for collaboration between practitioners and factory doctors, and the succeeding chapters, each written by a separate author, give the practitioner some insight into the work of the industrial medical officer.

H. M. Vernon briefly describes industrial poisons, but, as he points out, few of these will be found in any one factory. The difficult question of skin disease is skilfully approached by Alice Peters, but "contact" is a word neither used nor readily understood by those without experience of Royal Ordnance factories. In a helpful chapter chest diseases are discussed by A. J. Amor. Ethel Browning writes about toxic anaemia, which was recognized as a notifiable occupational disease only in 1942. But it is a sign of editorial lack of knowledge of industry that a separate chapter is given up to a technical discussion on back strain; on the other hand, the short contribution by D. C. Norris on malingering constitutes one of the best chapters in the book. T. Bedford writes on ventilation and heating in a simple yet fully informative style, and lighting problems are discussed by E. W. Murray. One major criticism is the lack of illustrations, to which a book such as this specially lends itself: for example, this takes away much of the value of P. Pringle's contribution on the works ambulance room. The final chapter—one perhaps that might have been put first in the series—is by A. I. G. McLaughlin on factory law in relation to health and welfare. As he points out, the principles of industrial medicine need legal backing to ensure that comparable preventive measures are practised in all factories throughout the country.

PHARMACOLOGY IN BRIEF

An Introduction to Pharmacology and Therapeutics. By J. A. Gunn, M.D. Seventh edition. (7s. 6d.) London: Oxford University Press.

Writers of short textbooks which while being short are accurate perform a most important service to medical education. There can be no doubt that Prof. Gunn, by this small book, has done a great deal to enable the harassed medical student to achieve some grasp of a subject the importance of which is growing. In many medical schools there is still no department of pharmacology; the student attends a few lectures by someone primarily occupied in clinical work, and for his examination is usually recommended to struggle with a large textbook. The result is that the student learns little of a fascinating subject which forms an excellent approach to the investigation of clinical problems. The first need is a simple book. Prof. Gunn has supplied this in an admirable form, for it is clearly written, in an interesting style, and surprising in the amount of matter it actually contains. Those who complain that it is incomplete should make sure of their ground by examining the book to see what information is missing. They will be surprised to find how little. If those treating patients are thoroughly familiar with this book alone it is certain that they would be on sure ground in the knowledge of how to use drugs.

Notes on Books

Parts IV, V, and VI complete the third edition of *Surgery of Modern Warfare*, edited by Mr. HAMILTON BAILEY (E. and S. Livingstone; 15s. each volume). They cover wounds of the central and peripheral nervous system, the trunk, the hand and foot, the eye and orbit, and the ear and air passages, and deal with surgery in subtropical countries and with administration and transport of the wounded. Part VI concludes with an appendix in which are viewed recent important papers on war surgery which have appeared while the earlier parts of this edition were in the press. In the earlier parts these later ones show evidence of much vision and include a number of new illustrations. The last illustration in the book, Fig. 1128, page 1077, is a photograph of Richard Lewisohn, now consulting surgeon to Mount Sinai Hospital, New York, to whom a well-deserved editorial tribute is paid, for to him we owe the citrate method of blood transfusion, which he announced in 1915 and which is now so universal. The modifications in the various editions of this work provide a key to the evolution of surgical practice in modern warfare, and to that extent is a history of surgery between 1939 and 1944. The third edition is the best that has yet appeared.

In *They Gave me a Crown* (Herbert Jenkins; 15s.) Dr. I. G. McGee has written his reminiscences of life as a ship surgeon, as an army medical officer, and as a doctor to a "world-famous industrial organization." The author's criticisms of the R.A.M.C. are too gentle and ill informed to make pleasant or useful reading. The latter part of the book is taken up with case histories of men justly suffering from mental strain or malingering. The interest these from a medical point of view is diminished by the absence of end-results: all trace is lost of the many men who "work their

ticket" out of the Army, usually after having given endless trouble to the authorities. The author designates mental examiners of such cases as "psycho-blokes." His book is more for the lay public than for the medical profession. We can imagine the former will find it amusing and entertaining so long as they do not take what he calls "sheer stupidity in the Army" too seriously.

It Came to Pass, by SIDNEY FAIRWAY (Stanley Paul and Co.; 9s. 6d.), is a medical novel that tells the story of a village boy whose ambition from his earliest years was to be a doctor. The time is the first half of the nineteenth century when modern scientific medicine was born. After service with an apothecary, the hero of the tale, Rufus Belden, becomes apprenticed to a doctor and later enters Guy's Hospital as a student. His subsequent professional career was dramatic and colourful enough to make an exciting story with a love thread running through it. The book includes a good account of the medical muddle in the Crimean War. The tale is well told and has been compiled from authentic sources such as *The Life of Florence Nightingale* and *The Biographical History of Guy's Hospital*. It is worth reading, and it emphasizes the striking progress that has been made in the care of the sick and wounded during the past hundred years.

The Cancer and General Research Committee of the Middlesex Hospital has sent us a folder containing collected papers by members of the staff published in various journals during the years 1942-3 and 1943-4. These reprints are prefaced with four classified tables of contents. The collection may be seen in the B.M.A. Library at Tavistock Square.

The book *Pathology and Therapy of Rheumatic Fever* by Leopold Lubitz, which was noticed in the *Journal* of July 29, will be issued in this country by William Heinemann (Medical Books), Ltd., early in September at 21s.

Preparations and Appliances

A GONIOMETER FOR MEASUREMENT OF SUPINATION AND PRONATION

Mr. JAMES PATRICK, F.R.C.S., orthopaedic surgeon, Glasgow Royal Infirmary, writes:

The instrument shown in the illustration has been devised for the measurement of supination and pronation movement of the forearm, as there does not appear to be any goniometer suitable for this purpose on the market. The pointer of the instrument is fastened on a spindle running through the axis of the drum, and inside the drum a weighted lever is fixed on the spindle in a position diametrically opposite to the pointer. As the drum and the scale rotate, therefore, the pointer remains vertical.

To use the instrument, the patient grasps the handle and stands against the wall with the elbows flexed to a right angle and with the forearms tucked in to his sides. Zero position is taken where the handle of the instrument is in line with the humerus. The surgeon gently holds the patient's wrists in order to guide the arm movements. The range of supination is read off on the affected side, and the instrument is then transferred to the normal hand and the supination range again measured. The limitation of supination is noted as minus x degrees. The same two measurements are then made for pronation and the limitation written down as minus y degrees.

This method of recording the measurement is a reliable one because supination and pronation movement is identical in range in either forearm in any normal individual. Simple direct measurement of the supination and pronation range on the affected side alone will not reveal when full movement has returned, and is useless for comparison of end-results between different patients because the rotation movement may vary enormously from one person to another.

By rotating both forearms simultaneously the patient is less likely to lean over to one side and so falsify the measurement, but in any case it is important to see that he remains standing erect. In performing pronation the patient has a tendency to bring the elbow away from the side, and this source of error must also be guarded against.

The manufacture of the instrument is in the hands of Chas. F. Thackray, Ltd., Park Street, Leeds.

'Sudermo' BRAND MESULPHEN

in the treatment of parasitic skin disorders

Applied externally, 'Sudermo' exerts a marked parasiticidal action, due not only to the contained sulphur but also to the hydrocarbon complex in which it is combined. Some indications include scabies; scabious eczema; seborrhæic dermatoses; pruritus; pediculosis pubis, corporis and capitis; acne. 'Sudermo' brand Mesulphen is a homogeneous, oily liquid containing approximately 25 per cent of organically-combined sulphur. It is readily

absorbed by the skin without irritation or damage to mucous membranes.

'SUDERMO' brand Mesulphen, bottles of 100 c.c., 4/6 (Purchase Tax 7d. extra), bottles of 1000 c.c., 33/0 (Purchase Tax 4/1½ extra). 'SUDERMO' brand Ointment containing 25 per cent Mesulphen and 25 per cent sulphur, glass jars of 20 grammes, 1/6 (Purchase Tax 2½d. extra). Subject to medical discount.

BURROUGHS WELLCOME & CO. (The Wellcome Foundation Ltd.) **LONDON**

Advances in Anticoagulant Therapy and Prophylaxis

TEMPARIN

Trade Mark Brand

DICOUMARIN

For the prevention and treatment of thrombo-embolic conditions

A new synthetic anti-prothrombic agent which when given by mouth temporarily prolongs the prothrombin time of the blood. This effect on the prothrombin time is protracted and thus obviates continuous administration. With this new anticoagulant one small dose daily is the general rule.

Temparin brand Dicoumarin therefore constitutes an important advance in the treatment of established thrombosis and

other vascular disturbances requiring anticoagulant therapy. It has been found particularly valuable as a prophylactic in all cases where the patient's medical history indicates a danger of post-operative thrombosis and embolism.

A 16-page booklet describing fully the pharmacology and indications of Temparin and containing a full literature survey will be sent on receipt of 1d. stamp.

Available in tablets of 50 mg. in bottles of 20 and 240

Manufactured by

HERTS PHARMACEUTICALS LIMITED, WELWYN GARDEN CITY

Telephone: Welwyn Garden 3333-6

AN IMPORTANT LOCAL ANAESTHETIC

● 'Anethaine' is a local anaesthetic with unusual and valuable properties, and is used in all forms of local anaesthesia.

In the effective dosage, the margin of safety is high. It has from 10-18 times more anaesthetic activity than procaine and is used in correspondingly lower concentrations.

Complete anaesthetic effect is of long duration, lasting from 1½ to 3 hours.

It has the very important property of high activity on surface application, and is thus the most suitable preparation for the anaesthetization of mucous membrane and wound edges prior to operative procedures or instrumentation, and in ophthalmology.

'Anethaine' is available in various packings for surface, infiltrative and spinal anaesthesia.

PACKS

Pot. der ... 1 and 5 grams
 Solution 2% ... 25 cc.
 (external) ... 25 cc.
 Solution tablets 10 × 0.1 gram
 Ampoules
 (Spinal) 1% 6 and 100 × 2 cc.
 Dry Ampoules
 (Spinal) ... 6 and 25 × 10 mg.
 Dry Ampoules
 (Spinal) ... 6 and 25 × 20 mg.
 Infiltrative
 (Pot. der) ... 3 and 25 × 100 mg.

SCOTLAND'S HEALTH

That a satisfactory level of national health was maintained in Scotland during the fourth year of war is shown by the Summary Report by the Department of Health for Scotland for the year ended June 30, 1944. Progress in maternity and child welfare was reflected in the rates for stillbirths (36 per 1,000 total births), maternal mortality (3.7 per 1,000 total births), and infant mortality (65 per 1,000 live births). These rates were the lowest ever recorded in Scotland, but there is much leeway to be made up yet; infant mortality is still high. Slightly over half of the infantile deaths in 1943 were due to diseases peculiar to early infancy—congenital debility, premature birth, malformation, etc. Of the remaining deaths one-third were attributed to pneumonia and one-fifth to diarrhoea. Maternity accommodation was extended during the year. At the end of June, 1944, 2,178 beds were available in maternity institutions—an increase of 333 on the preceding year, and 718 more than in 1938. A high neonatal death rate due to infections was experienced in both home and hospital—a problem now being thoroughly probed.

The deaths from the principal infectious diseases were 889 more in 1943 than in 1942—a rise due to an increase of 213 in the deaths attributed to whooping-cough and of 845 in deaths from influenza. The deaths from the other causes under this heading declined, and the totals for diphtheria, 59, and scarlet fever, 22, were the lowest ever recorded in Scotland. The incidence of dysentery of a minor type continued to increase; the notifications for 1939–43 were 1,132, 1,888, 2,429, 2,515, 3,425. Scarlet fever has also been more prevalent; the notifications rose from 13,792 in 1942 to 15,108 in 1943. Diphtheria notifications for the four years 1940–3 were 15,069, 12,395, 9,474, 9,255—a notable fall. The drive for immunization against diphtheria has slackened: fewer than 46,000 children were inoculated in 1943, and of these the 30,000 under 5 years of age comprise only one-third of the number of children who each year reach their first birthday. Propaganda should be intensified. The attack rate from diphtheria was four and a half times greater among the non-immunized than among the immunized, and the case fatality was nine times higher in non-immunized than in the immunized group of children: that is, the chance of dying from diphtheria was about 40 times greater among the non-immunized than among those protected by diphtheria prophylactic.

Tuberculosis mortality fell slightly: 3,959 deaths during 1943, compared with 3,998 in 1942 and 4,174 in 1941. But the number of new cases continued to increase, the notifications of pulmonary tuberculosis having steadily gone up from 4,657 in 1939 to 7,215 in 1943, and of non-pulmonary tuberculosis from 2,440 to 2,873. Returns submitted by local

authorities showed that by the end of March, 1944, over 1,400 persons were awaiting admission to tuberculosis institutions, of whom over 1,200 had diseases of the lung. The difficulty of finding room for them is one of staff rather than of beds: an additional 180 beds could be brought into use if the staff were available. This shortage of staff is a more serious problem in sanatoria and mental hospitals than in general hospitals. During the year over a thousand more nurses of all grades were employed in Scottish hospitals, but the Ministry of Labour's returns showed nearly 2,000 vacancies: the paucity of domestic workers made the situation worse.

The returns of first attendances at venereal disease clinics show that the large rise in incidence which began in 1941 has been checked. Compared with 1942 both syphilis and gonorrhoea declined by 500 cases in 1943, but the numbers of new cases—4,841 of syphilis and 5,437 of gonorrhoea—are large, and are 83% and 27% above the 1939 totals. The returns, however, are not an exact index of new infections, since not all infected persons attend treatment centres. Under Defence Regulation 33B there were 43 sources of infection named by two patients, and in only one case was it necessary to prosecute to compel attendance at a clinic. Efforts were made to persuade the 784 sources of infection named by only one person to be examined and treated.

The various social services were maintained. Expenditure on sickness and disablement benefits paid under the National Health Insurance scheme again showed an increase on that of the previous year. In the absence of an analysis of the various factors contributing to this increase it is not possible to state to what extent a rise in sickness has been responsible for it. The Supplementary Medical Service, which provides a thorough medical examination for ailing industrial workers and, if necessary, an investigation in hospital or treatment in a convalescent home, dealt with 4,655 workers during the year, 2,074 of whom were admitted to hospital and 1,033 to convalescent homes. The total number of pensions under the Contributory Pensions Act increased during the year by 11,748 to a total of 427,186. In January of this year 91,743 persons were receiving poor relief—7,387 fewer than in the previous year, and 15,158 fewer than two years ago. The rehabilitation centre for disabled miners established at Gleneagles at the request of the Ministry of Fuel and Power and the Miners' Welfare Commission has given treatment to 937 miners, but has not been fully used. The centre has accommodation for 200 men, but the average number in residence was only 80, and so the admission of patients other than miners is being considered.

Despite the present difficulties, progress has been made for a post-war attack on the unsatisfactory housing conditions in Scotland. The construction of 50,000 permanent houses during the first two years after the end of the war is aimed at, and, according to the report, the local authorities have now sufficient land for 56,000 houses. During the year reviewed only very slight damage to houses resulted from enemy action. In previous air raids over 70,000 houses were slightly, and 5,500 seriously, damaged, but all except 250 of the latter have been made habitable: 2,186 houses were completed and 2,837 were under con-

struction during the year reviewed. If the housing problem is tackled vigorously then the task of the Scottish Council for Health Education after the war will be eased.

SULPHONAMIDE SENSITIVITY

With the widespread use of the sulphonamides the problem of drug sensitivity has arisen in an urgent form, and it has been so serious a matter for the Army that a caution¹ has been issued against the indiscriminate use of the sulphonamides in infectious skin diseases. For this reason it is a welcome advance to be able to describe some of the circumstances which favour the development of sulphonamide sensitivity and to point to one or two ways in which it may be avoided. Fever, a rash, and conjunctivitis are the chief manifestations of sensitivity after oral administration of sulphonamides. They appear more frequently during a second course of treatment than the first, and when they appear during the first they are seen not at the beginning but usually after the fifth day. The rash is variable in character. In many cases it is an erythematous macular eruption; in others it is an inflammatory exudate eruption on the face, arms, hands, and legs. With sulphathiazole lesions very similar to erythema nodosum may be seen. An irritating dermatitis is particularly likely to occur after the local application of sulphonamides to the skin in the treatment of skin diseases or minor injuries.² At first it is confined to the area under treatment ("primary eruption"), but in the majority of cases other regions, to which no sulphonamide has been applied, become affected later ("secondary eruptions"). One of the most distressing features of the trouble is its long duration. Treatment in hospital for as long as fifteen weeks may be necessary, and the photosensitivity which sometimes accompanies the eruption may prevent outdoor work for even longer periods. A patient once sensitized may remain so for as long as five years, and only a very small dose is needed to cause and excite a reaction.

The clinical features suggest that the signs—fever, rash, and conjunctivitis—have their basis in an allergic reaction of some type rather than a simple toxic action due to an accumulation of the drug, and the suggestion was strengthened when the opportunity came for Rich³ to examine microscopically tissues from patients who had died after showing these signs. Then it was found that lesions were present in the vascular system which were like those seen in serum sickness in animals. This led to the hypothesis that the sulphonamides joined with a protein to form a haptene which sensitized the patient. There was already proof that sulphonamides form compounds *in vitro* with serum proteins, and Leftwich⁴ in experiments designed to test the hypothesis has now demonstrated that there is present in the blood serum of patients who have received one of the sulphonamides for more than five days an antigen which will cause an allergic type of response after intradermal injection in sensitive individuals. Thus one step in the process of sensitization seems adequately identified. The test is simple and involves only the intradermal

injection of 0.05 c.cm. of serum from a suitable donor the skin of the flexor surface of the forearm, with a skin injection of the control serum from the same donor inches below it. Both injections produce wheals which increase in size, reaching maxima in about fifteen minutes and a positive reaction is defined as one in which the wheal has a diameter at least 4 mm. greater than control wheal. It is a test simple enough to become routine practice in those cases in which sulphonamide sensitivity is suspected, and its specificity appears good enough for it to be a reliable tool as well as a simple one. The fact that a result is obtained in a few minutes is a great practical advantage. Using patch tests with different sulphonamides and other compounds with related structures, Park⁵ has begun the next stage in the investigation into the mechanism of the sensitivity. He has shown that some patients showing sensitivity give positive reactions with only one sulphonamide. Others give positive reactions with several sulphonamides and with sulphonic acid; as the radicle common to all these compounds $\text{NH}_2\text{C}_6\text{H}_4\text{SO}_2-$ he claims that this is the part of the molecule responsible for the sensitivity. A third group react to procaine, which has the radicle $\text{NH}_2\text{C}_6\text{H}_4-$ without a sulphononic group, and in these individuals the sensitivity is therefore less specific. These are interesting results to open up a line of attack which would repay energetic pursuit.

Several indications for the prescriber arise out of the experimental work and an analysis of case records.⁶ In dermatological cases it is the recommendation of the Army Medical Department that a sulphonamide should not be applied locally or be given by mouth for more than one week, and if sulphathiazole is given by mouth it is recommended that the course be limited to four days because of its greater tendency to cause reactions. Reactions are liable to occur if the drug is applied in the form of a thick paste (such as Lassar's) or a water-soluble cream.⁷ Nicotinic acid is of no value in treating the lesions, though there may be a deceptive likeness to pellagra, but high doses of the vitamin B complex have seemed to help. Because eczematous subjects are particularly liable to sensitization, and some of them may show an allergic response with the first dose, sulphonamides should not be applied to their skins, and oral treatment should be used only after due consideration of all the factors in each case. When inquiry before beginning a course of treatment brings out the fact that a previous course was accompanied by a rash or fever, the sulphonamide of the second course should preferably be a different one from the first, for there is in some cases at least a very strict specificity.

MORE QUESTIONS AND ANSWERS

Hard upon the results of the B.M.A.'s questionnaire come the details of two other attempts to probe opinion of medical services, the first addressed to medical students and the second to the public. The British Medical Students Association gave the lay press the results of its questionnaire last week, and unfortunately did not give the medical press

¹ Army med. Dept. Bull., No. 29, 1943, Nov., p. 3.

² Tate, B. C., and Klorfjan, *Lancet*, 1944, 1, 39.

³ Rich, A. F., *Johns Hopk. Hosp. Bull.*, 1942, 71, 123.

⁴ Leftwich, W. B., *ibid.*, 1944, 74, 26.

⁵ Park, R. G., *British Medical Journal*, 1944, 1, 781.

⁶ Dowling, H. F., and Lepper, M. H., *Amer. J. med. Sci.*, 1944, 207, 347.

⁷ Peterkin, G. A. G., *Lancet*, 1944, 1, 646.

an opportunity to record and comment at the same time. Their questionnaire, published in this week's *Supplement*, was drawn up with the assistance of the British Institute of Public Opinion and distributed to students through the medical schools. Only a quarter of the students sent in replies, which shows either an apathy about the future of the profession for which they are training or a disbelief in the effectiveness of their opinion. The number of students replying was 2,588, and 51% of these declared that their reactions to the White Paper were on the whole favourable. But in answer to the question "Would you enter the National Health Service as it is described in the White Paper?" 43% said "No" and 41% said "Yes", 15% could not make up their minds. On the other hand, 49% think that the White Paper scheme would enhance the quality of the country's medical service, and a smaller proportion—36%—believe it would suffer. On the 100% issue 72% voted in favour, and 89% approve of the principle of Health Centres. It is interesting to note that in the view of 67% the White Paper "places doctors under clinical control of local authorities". The power of the Central Medical Board to require a young doctor to give his full time to the public service in the early years of his career in case of need is looked upon as reasonable by 53% and unreasonable by 45%. As to payment, a majority—53%—favour a small basic salary plus capitation fees. On other money questions, the sale and purchase of practices should be abandoned in the opinion of 50%, while 37% raise no objection to this procedure. Sixty-three per cent. observe it would not be possible to set up in practice without incurring a debt, and 77% believed that financial assistance would be required to enable larger numbers to enter the medical profession. A very large majority—90%—consider that the political rights of doctors entering the National Health Service should be safeguarded. The opening statement of this question was as follows: "Some people paid by the State are debarred from politics or standing for Parliament."

The *News-Chronicle* of August 9 gave an account of a Gallup Poll into "what the public thinks". According to the newspaper account 75% of the panel patients questioned wanted to see some such system as N.H.I. retained if a National Health Service is not to be organized. This is quite a handsome tribute to the insurance doctors of this country, and suggests that those propagandists who represent panel patients as seething with discontent are doing what we have long suspected them of doing—that is, misrepresenting the present state of affairs in order to achieve their own ends. To the question "On the whole, would you like the idea of a publicly run National Health Service, or would you prefer hospitals and doctors to be left as they are?" 55% voted for N.H.S., 32% said, "Leave things as they are", and 13% said, "Don't know." This is hardly evidence of an "overwhelming" public demand for a change, although it shows that change is expected by a majority. Another question read as follows: "Who do you think should have most to say about the way medical services are arranged—the doctors, or the public through the Government?" 25% voted for doctors, 35% for the public, 32% gave an equal share to each, and 8% said, "Don't know." Eighty-six per cent. of those questioned said they had their own doctor to whom to go in case of illness and 63% said they could get a doctor's treatment free, while 37% had to pay for it, one presumes, therefore, that 63% of those questioned come under N.H.I.

Another interesting example of public opinion was shown in the debate held on August 3 over the wireless between the Chairman of Council (Dr H. Guy Dain), Sir Arthur Rucker (Deputy Secretary of the Ministry of Health), and

the potential patient (Flight-Lieut. W. P. Matthews), who summed up the reactions of a number of people when he said: "Well, now, this White Paper on health—it's a good thing—on white paper." There seemed, at least to one hearer, a quick response on the part of the potential patient to the point of view put forward so admirably by the Chairman of Council. When Dr Dain remarked, "We don't want doctors responsible to the Government or to local authorities—we want them responsible to the patient," Flight-Lieut. Matthews soon followed up with this interesting statement: "Yes, I see what you mean. Now I must say I've been bothered myself at the idea I've heard of people going to a Health Centre and just taking whatever doctor happens to be on watch at the time. Then perhaps you go a second time and you get a different doctor, and a third time and a different doctor, and it seems all wrong to me."

RENAL OSTEODYSTROPHY

Renal osteodystrophy is a new name suggested by Liu and Chu¹ for the disease commonly known as renal rickets. This disease, which also goes under the names of "renal infantilism," "renal dwarfism," and "renal osteitis fibrosa cystica," is characterized by rickets-like deformities, osteoporosis, dwarfism, albuminuria, anaemia, impaired renal function, and a high blood phosphorus. The pathogenesis of this disorder, the outstanding feature of which is osteodystrophy, is obscure. Because chronic renal insufficiency is responsible for the skeletal changes, which resemble those of rickets, the condition was originally known as renal rickets. This term identifies the bony changes with those of rickets, but they are not identical, although the radiographical appearances and gross skeletal deformities are similar in the two diseases. And rickets responds to vitamin D, whereas renal osteodystrophy does not. The terms "renal dwarfism" and "renal infantilism" are equally unsatisfactory because they emphasize a feature which is absent when growth is complete and do not indicate the osseous changes. Albright, Drake, and Suck² are inclined to consider osteofibrosis as the essential pathological skeletal lesion, and so introduce the descriptive term of "renal osteitis fibrosa cystica." Certainly rarefaction of bone and cystic absorption are the most prominent radiological features. Renal osteodystrophy, however, appears to be a good term, and at least consists of two words only. Metabolic studies by Liu and Chu on five patients confirm the low urinary output of phosphorus, the high level of serum phosphorus, and the renal failure, the phenolsulphonphthalein excretion through the kidneys averaged only 6% and the urea clearance only 10% of normal. Increased intake of phosphorus resulted in increased excretion into the gut, where it interfered with absorption of calcium, so that the patients were in negative calcium balance. Liu and Chu also demonstrated the existence of chronic acidosis, which in turn leads to a lowered blood calcium. In man and animals it has been shown experimentally that acidosis produces decalcification.³⁻⁶ These observations provide a rational explanation of the pathogenesis of renal osteodystrophy. The disease has its origin in renal insufficiency; this hampers the urinary excretion of phosphorus, the blood level of which is raised. Increased phosphorus excretion into the gut interferes with calcium absorption, the calcium forming insoluble calcium phosphate. Renal insufficiency, by causing retention of phosphate, sulphate, and other acid

metabolites, causes base to be taken up, with resulting acidosis, which in turn further limits absorption of calcium. The low calcium intake in the diet of patients studied by Liu and Chu aggravated the condition still more. All these factors contribute to produce a low blood calcium and finally skeletal decalcification.

Although vitamin D is specific in the treatment of true rickets and of osteomalacia, it is ineffective, even in massive doses, in renal osteodystrophy; in fact, it may make the condition worse by mobilizing phosphorus from the tissues. Liu and Chu found that A.T.10, or dihydrotachysterol, one of the products formed by the prolonged irradiation and hydrogenation of ergosterol, was remarkably effective in improving the intestinal absorption and retention of calcium and phosphorus in their patients. They were, however, unable to observe recalcification of the bones, possibly because treatment was not continued long enough. Since A.T.10 is also effective in true rickets, it can apparently mobilize calcium in the presence of renal insufficiency, whereas vitamin D cannot. There was some evidence that iron improved absorption of calcium in the patients studied, presumably by facilitating the excretion of excess phosphorus in the gut by the formation of insoluble iron phosphate. The administration of alkalis such as sodium bicarbonate or citrate also resulted in improvement, probably by preventing acidosis. The ultimate prognosis in patients with renal osteodystrophy is poor, but the treatment suggested by Liu and Chu—a limited-protein, low-phosphorus, and rich-calcium diet, alkalis, A.T.10, and iron—is certainly worthy of trial.

DEHYDRATED VEGETABLES

Before the war vegetables were often regarded as accessories to the more fundamental foods such as meat, fish, bread, and milk and its products. To-day, however, the shortage of these basic foodstuffs and of imported fruits has brought into proper perspective the importance of vegetables—especially as sources of vitamins and mineral salts. It is, for instance, now generally accepted that during most of the year in wartime the greater part of our civilian population depends solely on vegetables for its supply of vitamin C (Harris and Olliver¹). The importance of supplying vegetables to the fighting Services is also fully recognized. However, transport and storage of these foods provide a problem which, while significant in peacetime, assumes tremendous proportions in time of war. Green vegetables are especially difficult, as they readily wilt and lose both palatability and nutritional value. Moreover, they contain over 90% of water, and their transport and storage must therefore be regarded as an extravagant use of valuable shipping space. The answer to these problems was found in dehydration. Unlike the old-fashioned drying methods, dehydration is a scientifically controlled process by which colour, texture, flavour, and nutritional value of the raw vegetables are well maintained. Since ordinary drying methods have a damaging effect on some of the nutritive constituents, this aspect of dehydration has received special attention both in the United States and in this country. Tressler, Moyer, and Wheeler,² for example, working in America with factory-produced dehydrated vegetables, have shown that there is a high percentage retention of carotene on dehydration. Dehydrated cabbage was also found to retain nearly all its initial vitamin C and contained over 300 mg. ascorbic acid per 100 g. Similar data, much of them unpublished, have been collected for factory-produced material in this

country. Two important stages have also to be considered beyond the actual production—i.e., storage and reconstitution, which latter is the soaking and cooking of the dehydrated vegetables. As to storage, various factors such as moisture content, temperature of storage, and presence of oxygen have been shown to affect both culinary quality and nutritional value (Tomkins *et al.*³). These factors can be largely controlled by suitable packaging, and the use of cans is generally adopted. Nitrogen is also used for packing those vegetables likely to be affected by storage in air. Dehydration and storage processes can be controlled scientifically, but the colour, flavour, texture, and nutritional value of the reconstituted material all depend ultimately on the efficiency of the cook. This is of course equally true of fresh vegetables, and conditions of cooking have therefore to be identical when comparing the two materials. The effect of variation in such conditions upon the nutritional value of dehydrated vegetables has been studied by several investigators (Fenton *et al.*⁴; Allen and Mapson⁵), and it is generally agreed that reconstituted dehydrated vegetables have a high food value. Palatability is too closely linked with food value to be ignored, and the experience of Macrae⁶ with the use of dehydrated vegetables in the R.A.F. must be regarded as of special importance. He found that the dehydrated foods not only had a higher content of ascorbic acid but were less likely to be left on the plate than were cooked fresh foods. Whatever, therefore, the post-war prospects of dehydrated vegetables, they are undoubtedly invaluable at the present time for the part they are playing in maintaining the health of men and women in the Services.

PENICILLIN FOR CIVILIANS

As we announced in the *Journal* of July 22 (p. 119), a limited supply of penicillin will soon be available for the treatment of civilians. So that available quantities may be used to the best advantage the Ministry of Health has decided to invite the Medical Faculties and Schools of Universities to be responsible for its use and distribution. By allotting to each school an area corresponding in general to the Civil Defence Region in which it is situated the whole of the country should be covered. In the London Sectors the medical school that controls the Sector will be responsible for the Sector area, and if, as occurs in four of the Sectors, there is a second medical school, that school will be responsible only for the patients that normally seek admission to its associated hospital. Most of the cases that should have penicillin will be in-patients, and if the hospital is not one of those granted a supply it should apply to the medical school or the associated teaching hospital of the area, giving full details of the diagnosis. If apparently suitable it might still be necessary for the case to be transferred for further investigation to the teaching or other approved hospital, whichever is most convenient. If, however, the patient is not a hospital in-patient but is in private care the practitioner should arrange for his admission to hospital, which would then be responsible for the diagnosis and for the application for penicillin to the medical school or teaching hospital of the area. If any difficulty should occur in obtaining admission to hospital the practitioner could apply direct to the medical school, which would, in a suitable case, arrange for admission to an approved hospital. Supplies of penicillin are being sent to Scotland and Northern Ireland, which have arranged for their medical schools to be responsible for its use and distribution.

MEDICAL EXPERIENCES IN THE BURMA WARFARE

A correspondent in England sends two extracts from a long letter written to him on June 23 by his junior partner, who is anaesthetist in a mobile surgical unit. The first gives a vivid account of active service in Burma seen through medical eyes. The second puts the point of view of a young man who had not been long in general practice before the outbreak of war and who is concerned about his position after demobilization.

First Extract from Letter

I am writing from Srinagar in Kashmir, where we are just finishing a fortnight's holiday. We have been staying in a houseboat and enjoying the most delightful weather and scenery it has been my fortune to experience. The journey here from Burma has been appalling, but Kashmir has justified our high expectations of it and has been a very pleasant break from jungle life. I now claim to be somewhat of a veteran in that mode of living, having completed nearly two years in the bush and frankly I am getting a bit tired of it, especially during the lulls in activity. It is difficult to know what to write to you about, but perhaps as an old soldier you may be interested in a few aspects of our type of warfare and in a few of the non-censorable episodes. I hope I can avoid histrionics.

As you know, our recent campaigns have been much more successful than the 1942-3 variety. We have, I think brought jungle warfare right up to date and seem to keep on learning new tricks of our own, and have long since explored the depths of our opponents' ingenuity. At any rate it is a game in which you judge the results by the counted bag, and Burma, or at least the part I have been associated with, stinks to high heaven of Jap dead. Their philosophy of the honourable death reaps us a rich and handsome harvest. One cannot deny their courage. I don't think the blighters are afraid of anything, but they have not managed to put this virtue above the animal plane, and, instead of being an asset, as it was at one time in the early days of the war, it has become one of their biggest debits. They walk into death, usually in the form of a British or Indian soldier sitting quietly and obeying the dictum about not shooting or bayoneting until he sees the whites of their eyes. I remember the early days in Burma when we only had to hear of near-by Japs to feel our hearts flutter. The wondrous stories which we were told, and we told of what amazing tricks Nippon had up his sleeve had precisely that effect—good propaganda for exploiting the fear of the unknown. Now we recognize that he is a bitter fighter, and a fighter to the end, but as a simple mathematical proposition he is an inevitable loser. He is not easy to eliminate. It requires an abundance of courage on the part of our troops to undertake these battles to the death. There is no White Flag out here, and the British soldier—the average one—has a surplus of courage. The morale is absolutely terrific. All are extremely proud of our Command and Army, and faith in the leaders is not lacking.

As an example of what is being done at one time a group of us were cut off by the Jap for some weeks—we were a pretty good sitting target—and things were decidedly unhealthy. However, our air supplies arrived regularly on the dot, and the thing that impressed me most was our daily newspapers were dropped in adequate quantities and on the day of publication! And the powers that be did not forget to parcel in plenty of beer, and magazines, etc. for the wounded. Things never looked so bad after one had been able to glance at the paper and sip one's beer before turning in. During this particular 'do' I—and myself probably established a record for front line operating. We could actually see the wounded being wounded, and usually had them outside our theatre in 5 or 10 minutes. I think that on the balance between conditions of work and time we (I am not boasting, it is merely circumstances) saved more life and limb than we could ordinarily have done at any rate we got our abdominal figures up to 70% survival rate, and you can imagine what the peace and quiet for nursing was like. Fortunately our unit came out of this 'do' fairly intact (at one time we were virtually

captured), but we did have the misfortune to lose our Indian assistant surgeon, who was captured and later shot, having gone through a pretty brutal period in between. The Japs are, believe me, quite subhuman.

Our living conditions by force of Nature are pretty foul—I cannot imagine a worse climate—but we manage to make the best of them, and are being pretty successful in combating the many prevalent diseases. The troops are well educated in preventive medicine, which is a continual struggle alongside the other and major one, and once more we are winning the day. The old story of the medicals being a rope round the combatants' neck is not true out here, one is offered so much help and assistance from the other arms of the Service that one is continually and regrettably refusing aid! They told us at Crookham never to expect help without having to fight hard for it. Quite untrue!"

Second Extract

"I am afraid I have lost interest in the 'White Paper'—soldiering and medical politics seem to clash a little—but have read the abbreviated official report and found it wordy and uninspiring. It does not give one much idea of what is to happen to a practice like ours, which, candidly, is all I am now interested in. I am more and more looking forward to getting settled down at work again and anxious to know if the Government is going to allow me. It seems a hell of a time to have been away from one's work, and impossible to guess when one may get back to it. What do you think will happen?"

LONDON COUNTY COUNCIL

The London County Council proposes to participate in the scheme of the County Councils Association and the Association of Municipal Corporations (*Journal*, Aug 5, p 187) to set up a National Ophthalmic Research Council, and will contribute a sum up to £2,000 for a period of five years towards the funds of the council on the understanding that the scheme will then be reviewed in the light of the relevant circumstances.

It is proposed for the present not to fill the position of deputy medical officer of health and deputy school medical officer vacant by the resignation of Dr Andrew Topping. In the meantime Dr R C Harkness, one of the two principal medical officers will act for the medical officer of health during his absence, and a third principal medical officer will be appointed. It is also proposed to second to the central office staff of the County Council an experienced medical superintendent of one of the hospitals for a period up to six months in order that he may undertake the visitation of all the hospitals, make contact with the staff, gain information generally with regard to the hospitals service, and report on the desirability of any changes or improvements which may appear to merit consideration in relation to the proposed National Health Service.

The Mental Hospitals Committee of the LCC has been considering the question of medical staff in the mental hospitals service undertaking remunerated and unremunerated outside work, including work at voluntary hospitals. Full time medical officers at hospitals and institutions and at the central pathological laboratory will be encouraged to undertake outside work, such as occasional lectures to students or to societies, or to act as examiners to outside authorities, provided that permission of the medical officer of health is obtained for remunerated work in all cases, and that in the case of unremunerated work permission is obtained from the medical superintendent of the hospital or the director of the laboratory.

It was reported to the last meeting of the Council that the special scheme for transferring expectant mothers to emergency maternity homes outside London shortly before confinement, which has been in operation continuously since the summer of 1940, has now had to cope with a sudden and heavier demand, it has also been extended to 18 additional evacuation areas. The shortage of midwives has created a difficulty. The scheme, however, has operated successfully, and in the course of six weeks over 2,100 patients were sent to maternity accommodation specially reserved for them.

BEIT MEMORIAL FELLOWSHIPS FOR MEDICAL RESEARCH

Prof. T. R. Elliott's Retirement

Prof. T. R. Elliott had already served as a member of the advisory board to the Beit Memorial Trustees since 1922 when in 1930 he succeeded the late Sir James Kingston Fowler in the important work of the board's honorary secretary. During the fourteen years which have followed, his intimate experience of the working of the Trust, and the skill and labour he has devoted year by year to the applications and reports which have fallen to be considered, have been of the highest value to the work of his colleagues on the advisory board, and of the trustees to whom he has carried their recommendations. In 1935 he himself became a trustee. The continuity of the policy of the trustees and their advisory board, and the ease of its adjustment to changing conditions without any lowering of standards or narrowing of aims, have owed much to Prof. Elliott's enlightened enthusiasm for the work of the Trust, his pride in its achievements, and his vision of its possibilities. And he has acted as a friend and adviser to many of those whom he has helped to elect to Beit Memorial Fellowships, two to three decades and more after he had held one himself (1911-12).

When Prof. Elliott retired in 1940 from the professorship of medicine at University College Hospital Medical School he had intended to relinquish also his work for the Beit Advisory Board; but the successor to the secretaryship already nominated found that war demands claimed his whole time, and Prof. Elliott was persuaded by his colleagues to continue further his services to them and to the Trust. Now at length he has been obliged to claim a rest from duties carried so long and with such distinction. He hands on a fine tradition to his successor, Dr. A. N. Drury, director of the Lister Institute.

CONTROL OF NARCOTIC DRUGS

The Permanent Central Opium Board held its 44th session in London at the end of July under the presidency of Sir Atul Chatterjee. The other members present were: Sir Malcolm Delevingne (United Kingdom), Mr. J. H. Delgorge (Netherlands), Dr. George Woo (China).

In a communiqué the Board states that it reviewed the statistical information recently received and also the measures of control over the trade in and manufacture of narcotic drugs which were under consideration by the competent authorities for countries which are to be liberated. Three months ago the Board issued a report containing recommendations as to the action which, in its opinion, should be taken to minimize the potential dangers in the present situation. The Board understands that its recommendations have received the attention of the military authorities concerned with Western Europe and that decisions have been taken which in substance are in accord with the Board's recommendations and which will be carried into effect as occasion arises. It hopes that decisions will be taken for the other theatres of war at an early date. The danger is not confined to Western Europe, and the Board emphasizes the importance of adequate measures to the same end being taken in all the other theatres of war, especially in South-Eastern Europe and in the Middle and Far East. For the full exercise of its supervisory functions, information should be available to the Board as to the steps progressively taken in the liberated areas—e.g., Italy—for the establishment of the national control.

PRESTON HALL

In 1925 Preston Hall, the British Legion village at Maidstone, was taken over for the treatment and care of tuberculous ex-Service men. In 1934 Douglas House, near Bournemouth, was acquired for the treatment of chronic ambulant patients, and in 1943 the same council of management acquired Nayland Sanatorium, near Colchester, for the reception of cases of tuberculosis among Service and ex-Service women. The number of sanatorium beds at Preston Hall is 175, with 139 houses in the village for ex-patients, and the other two institutions have a further 290 beds. The medical director, Dr. J. B. McDougall, in his report for 1944, says that from the administrative

standpoint the greatest problem has been to preserve a balance between the medical and rehabilitation aspects of the war Orders for the industries which are carried on at all the places have come in at a rate which has overshadowed anything known in peacetime, but the temptation to overwhelm industries with orders has been resisted. Any tendency to expand the industrial aspect of the village settlement must never be allowed to prejudice its main function, which is care and treatment of tuberculosis. In the near future it is expected that 2,000 cases of tuberculosis from the various Service departments will have passed through the wards. Certain of the wards in an E.M.S. hospital have been allocated for their reception, and the collaboration with the military wing has been close and efficient.

Correspondence

Freedom to Publish

SIR,—The letter of the Secretary of the B.M.A. addressed to voluntary hospitals and local authorities (*B.M.J. Supplement* Aug. 12) advocating that medical officers should be free to publish scientific material is much to be welcomed, but with the reservation that the letter does not go far enough. The inclusion in the last paragraph of the words "in other ways seems to acknowledge the need for some amplification."

The writer of the annotation in the same issue of the *Journal* (p. 219) is more definite; he says truly: "In the profession of medicine there are many matters of interest and importance to doctors that cannot be described by the words 'purely scientific and technical.'" The latter quotation is the phraseology of the L.C.C. amendment. In no way does it remove the censorship on publications—anything in the least critical that may offend the bureaucrat can still be censored as not sufficiently pure. Unfortunately the wording of the B.M.A. letter invites further such amendments or *ad hoc* resolutions of similar character.

The confusion that is occasioned by the term "scientific freedom" is well illustrated by the writings of Geoffrey Bourne who has developed in some twelve columns of the *Journal* the theme of the B.M.A.'s letter (see *B.M.J.*, Feb. 20, 1943; May 29, 1943; June 3, 1944). Thus, "No system is to be tolerated in which free speech on medical matters, free criticism of medical affairs, and free publication of scientific work are discouraged or in the slightest way impeded" (*B.M.J.*, Feb. 20, 1943); "Complete freedom of speech, criticism, and medical practice must be retained. Any member of a State service must have the right to speak his mind about his political or professional superiors on any question of medical science, practice, or policy" (*B.M.J.*, May 29, 1943); "In any State Medical Service all medical men shall have full right of expression and criticism in medical matters" (*B.M.J.*, June 3, 1944). In spite of this consistency the three articles must leave any student extremely confused, for while advocating this active role of publication and criticism Geoffrey Bourne apparently wishes to keep quite free from politics: "Medicine and science must not be political" (*B.M.J.*, May 29, 1943). How can a medical man be free "to speak his mind about his political or professional superiors on any question . . . of policy" without being political? This contradiction is marked throughout the articles, and the confusion is in no way clarified by such phrases as "Politics can often be turned on like gas, but science cannot be turned on like water" (*B.M.J.*, May 29, 1943). In his hypothetical campaign for the exposure "of the scandalous tuberculosis services of Blimpshire" (*B.M.J.*, June 3, 1944) Geoffrey Bourne follows well-recognized political methods.

The truth is that scientific observation and publication have an influence on politics. Some scientific articles have a large political content, some have little. It would not be very political to-day to publish an article on the earth's movement in relation to the sun, but Galileo found it political enough. Why did Harvey delay publishing his observation on the circulation of the blood for so long? An article to-day on the technique of the Wassermann reaction has little political con-

tent, but many scientific articles bearing upon the diagnosis and control of syphilis could have a great deal.

What we need to establish is freedom to speak and write on matters that affect our profession whatever the political implications may be. This is the prophylactic against bureaucracy and would do much to ensure a democratic medical service. I emphatically agree with Geoffrey Bourne that "the democratic system of medical service is entirely compatible with State control" (*BMJ* Feb 20, 1943)—I am, etc.,

King's Langley Herts

TOM GARLAND

The Kenny Treatment of Poliomyelitis

SIR,—In the *Journal* during the past two years there have been various references to the Kenny system of treating poliomyelitis. From these articles it would appear that a great deal of enthusiasm had been aroused, mainly in the popular press, but also in some medical centres of the United States. You published two critical reviews, and the conclusions seemed to be that the Kenny methods and theories did not justify the attention that was being paid to them in the United States, and comment was awaited from American authorities who could be trusted to give a sound view upon the matter.

It will interest you, I think, therefore, to have these extracts from a report of a committee of the American Orthopaedic Association, given to me in a personal letter and probably paraphrased.

1 "Muscle spasm." Stiffness in the neck and back has long been recognized, and it disappears spontaneously. There is seldom spasm in the extremities, and this has nothing to do with the final result.

2 "Mental alienation." To say that the flaccid muscle is normal is not true. It means a temporary paralysis or stretch paralysis, and was discussed by Jones in 1911.

3 "Co-ordination is disorganized." This is another term for muscle incoordination and was used in 1912.

4 "Paralysis." It is thought that the handling necessary for the Kenny treatment might make the patient worse. Putting the patient in the normal standing position has been recommended for the past 30 years. Heat has been used for many years. Hot packs do not always relieve the pain. The pain can easily be relieved by other measures. In some cases the hot packs seem to prolong the muscle spasm. The spasm disappeared in some cases when the packs were stopped. She insists that a very rigid technique should be followed for twelve hours each day. This is not essential.

5 "Restoration of muscle function." Jones and Lovett many years ago advised the same in their textbook.

6 "No braces or splints are tolerated." Splints are beneficial in some cases. The patients should be allowed to wear braces and be able to discard crutches.

7 "No respirator should be used." The committee thinks they should be used when needed.

8 "The family are told that the Kenny method would have prevented paralysis." She tells parents that if she could have treated the patient early it would not have gone on to paralysis. This is wrong. Some of her patients which she treated early before they were paralysed developed severe paralysis. She does not recognize spontaneous improvement. She claims that it is her method which "cures" the patient. We know that 80% improve spontaneously.

9 "Muscle tests." Her lack of muscle tests is to be condemned. Muscle tests carefully done are not harmful. She is the only one who thinks they are harmful. She says that only 13% recover by the other methods. This statement is wrong. She has been shown abundant evidence in medical literature that from 70 to 90% recover by the orthodox methods.

10 "Deformities." She says that no deformities have developed following her treatment. Her cases have not been followed long enough. Severe paralytic scoliosis does not show up until after three years. Her cases will need to be watched longer. Contractures of the muscles must be prevented early.

In summarizing the report Ghormley said "A study of 750 cases showed that continuous hot packs are of questionable value, and that it is a waste of man power and hospital beds."

Gill stated that the members of this committee had different views about this treatment at the beginning of the study, but that they were all agreed by the end of the study.

Albert Key said "The concept of Miss Kenny is wrong. What is good in her treatment is not new, and what is new in it is not good." He thought that another paragraph should have been added to the report making it still more clear that the committee did not recommend her treatment.

—I am, etc.,

Exeter

NORMAN CAPENER.

Registration of Specialists

SIR,—I have just read Lieut. Col. Gear's instructive paper read and considered in conjunction with the 1,509th "Old and True" in the *Times* of Aug. 5. The relevant part of the quotation is "it requires art in order to persuade, none is needed in order to command . . . When the power that makes the laws and the power that applies them are identical, laws are useless. Every exercise of authority that goes beyond what is really necessary is a tyranny."—Turgot.

And, having read the "Old and True," let us turn to the *Journal* (p. 188) and, after perusing it, ask ourselves whether the suggested registration of specialists does not go beyond what is really necessary.

First, it would be reasonable to settle the problem of what (if anything) is wrong about our specialists. Secondly, we might reasonably ask ourselves whether we are likely to get better specialists by making young men and women decide on a specialist career immediately after (or even before) they have become qualified. And, thirdly, we must face the fact that, if the future registration of specialists is to depend upon the possession of higher qualifications and upon a period of postgraduate training (but still *in statu pupillari*), we shall have two distinct branches of the medical profession: one firmly and permanently fixed in the groove of general practice, and the other in the even deeper groove of specialism. No passage from the former to the latter group would be possible, except perhaps for a very small number of general practitioners with private means, who could give up lucrative work for five years in order to be subjected to specialist training.

There are other features of the suggested legislation which should make us (and our leaders) pause. Thus, there could never again be another Sir James Mackenzie, who, graduating from a busy general practice into specialism, became the father of modern cardiology. Of course, there may be those who would contend that he would have been a still greater man if he had had five years of postgraduate training in his specialism. I doubt it, and, I imagine, Sir, that you do also.

Then again, we should remember that, learned though the members of the General Medical Council undoubtedly are, they have not been endowed by statute or (so far as I am aware) by miracle with the gift of prophecy. And, as they have not been so blessed, it is difficult to see how it can be assumed that they will foresee and cater for new specialties that may be needed in the future. I am, of course, presuming that it is not supposed that the book of knowledge is already completely written.

One would, not unnaturally, like to know whether the specialist of the future will be allowed to examine and even treat maladies that are not included (by, I suppose, delegated legislation) in the schedule of diseases he is licensed to deal with. Or must, for instance, the haematologist (if haematology be permitted the sacred status of a specialty) who is treating a patient with pernicious anaemia call in a neurologist if the patient develops signs of subacute combined degeneration of the cord? Or must he have the continuous collaboration of a neurologist, because he (the haematologist) is not supposed to be able to recognize the early (or, indeed, any other) stages of the nervous complication?

Of course the present suggestions are for the interim period, and it will not be until later that the compulsory postgraduate training will be essential for admission to the register of specialists. At present persons recognized by their colleagues (who know them) as specialists will be recognized as such by the General Medical Council (which does not know them). But the day will come when some youngster, after his five years of postgraduate training, will be admitted to the specialists' register and will tell his older colleague that he himself is a qualified specialist while he (the older man) is only a registered one. Do not tell me that this is impossible: both dentists and State-registered nurses have met the same difficulty.

May we not, Sir, with all respect, ask the Mother of Parliaments to refrain from converting herself into a purely legislative assembly, so that she may have time to perform her centuries-old duty of protecting the people from infringement of their ancient rights by the executive?—I am, etc.,

London W 1

A. PNEY.

The Surgeon and the Anaesthetic

SIR,—Recent correspondence concerning the respective merits of old and new methods of anaesthesia seems to emphasize once again that the safety of any anaesthetic depends chiefly on the technical skill and clinical judgment of the anaesthetist. Like most anaesthetists I use a little chloroform on occasion and under certain special conditions, but Dr. Herbert Brown's belief (Aug. 5, p. 191) that light chloroform anaesthesia is not especially dangerous only holds good when the skill and judgment of the administrator are above suspicion. In incompetent or inexperienced hands chloroform is potentially an extremely dangerous and toxic drug, and for this reason many authorities recommend that it should be banned from general use.

Sudden death during light chloroform anaesthesia is particularly prone to occur in two classes of patient: (a) the violently excited and struggling patient, with an obstructed airway due to pharyngeal or laryngeal spasm; and (b) the pale, "quiet" individual (usually under 30) suffering from general debility and obvious oxygen lack. In the former case a struggling and cyanosed patient suddenly takes a deep breath of concentrated chloroform vapour with the customary well-known result. In the second group the tidal respiration may be so shallow that the anaesthetist (often an inexperienced house-surgeon or practitioner) sometimes does not know that the patient is dead until an onlooker chances to remark that "The patient doesn't look very well, doctor!" Catastrophes such as these are less likely to occur if care is taken to maintain a free airway and oxygen is administered continuously before and during induction, but the only certain way to prevent them is not to use chloroform.

The technique of administration and precautions to be adopted in injecting pentothal have been very fully described in the literature, and if mishaps occur due to faulty judgment on the part of the administrator the remedy is not to stop using pentothal but to employ a more experienced anaesthetist. When injected intermittently in small doses and with due regard to the condition of the patient the danger of overdosage is very remote, especially if oxygen is administered throughout. When trouble arises it is generally because insufficient care has been taken to keep the tongue forward and the airway clear. Pentothal should not be used if the airway is likely to become obstructed, or if there is a possibility that haemorrhage from the mouth or post-nasal space may set up laryngeal spasm; if this should happen endotracheal intubation must be carried out at once. Lastly, it is safer to limit the dose according to the condition of the patient. Personally I prefer to use pentothal for induction of anaesthesia, or short procedures lasting not longer than 20 minutes.

Dr. Brown's apparent surprise at the sensible precautions suggested by Dr. Murphy (July 15, p. 93) and others is surely unnecessary. Oxygen, cardiac and respiratory stimulants, etc., should always be available when an anaesthetic is being administered, whether the method of administration be intravenous, inhalational, spinal, local, or even no anaesthetic at all. The last contingency is by no means an exaggeration. Not long ago, when I was preparing to inject pentothal for a dental case, the patient suddenly went off in a "dead faint" (either at the sight of the needle or myself, I am not sure which!), and, at my suggestion, the extractions were completed by a slightly horrified dentist, while 100% oxygen was administered under pressure through the nose-piece of the McKesson apparatus. However, I do not recommend this mode of anaesthesia, although, from the standpoint of economy, it has certain advantages.—I am, etc.,

Newcastle-upon-Tyne.

PHILIP AYRE.

SIR,—Having read Dr. Herbert Brown's letter with interest, may I offer the following criticisms from the point of view of a specialist anaesthetist.

1. Quoting Dr. Elam (Feb. 19, p. 263), Dr. Brown says, "Modern anaesthesia will become (if it has not already done so) far more dangerous than chloroform anaesthesia at its worst." Yes, in unskilled hands. All potent drugs—chloroform, trilene, and cyclopropane (which Dr. Brown does not mention; why?), pentothal sodium and allied drugs—are dangerous in unskilled hands. Is it not those who have done a few simple

cases successfully with a certain method—e.g., pentothal sodium—who are apt to develop that false sense of security described by Dr. Elam? The more one uses these drugs and discovers their variations from case to case the more wholesome respect one has for them.

2. Dr. Brown says, "A new and relatively untried drug such as pentothal. . . ." This drug came into wide use in November, 1937, as a result of published reports. Its forerunner, evipan sodium, had been in use for several years previously. As to the relatively "untriedness" of the formidable number of Allied casualties in this war very few requiring anaesthesia fail to have pentothal sodium. The number of administrations, therefore, in the past four years alone must be enormous.

3. "The surgeon should choose the anaesthetist who will give the anaesthetic he prefers" ("he," I presume, meaning the surgeon) "in the manner required and not continue the administration unduly." If, as is implied by this, anaesthetists must be one-method men or mere technicians, let us have nurse- and orderly-anaesthetists to carry out Dr. Brown's instructions implicitly!

Most modern surgeons, I believe, prefer an anaesthetist with experience in the use of all anaesthetic and analgesic drugs (ancient and modern) by all recognized methods and routes, who can be relied on to give that drug or combination of drugs most suitable to each patient by such methods, routes, and apparatus as may be most expedient, and so to submit the patient to the surgeon that the operation may be most easily performed with the least after-effects. Such a standard cannot be attained without much full-time study and experience. Modern anaesthetics require a full-time specialist. They cannot be successfully practised as a busy G.P.'s hobby. (In compiling the proposed "Register of Specialists" it would be well that this point were considered.)

Finally, whatever the advantages and dangers of that old "bone of contention"—chloroform—I never use it because it makes the anaesthetist very sick, and it is as well to credit one's patient with at least as much sensitivity (in all respects) as oneself.—I am, etc.,

Wallasey.

UNA M. WESTELL.

Progesterone

SIR,—I am grateful to Dr. Richard Sands for pointing out that in 1932 Mr. Christie Brown put forward the theory which I outlined in the *Journal* of June 24.

My letter was partly by way of being a disclaimer, as I was afraid Dr. Walter Calvert might possibly imagine that when I made a personal communication to him along the same lines I was claiming some originality for the theory so far as I was concerned. In a subsequent letter Dr. Calvert seems to imagine that I imputed that he, Dr. Calvert, was claiming originality for the theory. I think that if he reads my first letter again he will see that I made no such implication, but merely made it clear that his views might be based on my personal communication to him, and that the views in that communication were not my own, but were, so far as I knew, those put forward by Mr. Barton Gilbert.

In suggesting that this theory had been originated by Mr. Gilbert I have since learnt that in the main I was in error. In the *Journal of Obstetrics and Gynaecology of the British Empire*, Autumn, 1932, appeared an article by Mr. Christie Brown entitled "The Posterior Pituitary Gland in Pregnancy." Briefly, his theory suggests that the decreased sensitivity of the uterus to the posterior pituitary during pregnancy is due to the secretion of the corpus luteum—as has been pointed out by H. Knaus—and that in the same way one finds relaxation of the intestine leading to constipation, relaxation of the blood vessels with lowering of the blood pressure, and the production of varices and also early morning sickness.

As it has been pointed out that Mr. Gilbert did not originate this part of the theory which I outlined, I may well be in error in suggesting that he was responsible for the rest of it as well. Once one has grasped the underlying principle of a theory of this sort, it is very easy to extend its implications; so who was first responsible for suggesting that albuminuria of pregnancy, primary uterine atony, accidental haemorrhage, and pyelitis of pregnancy were due to a similar cause I cannot definitely say. As the outlines of the theory appear to be moderately well known, it may well be that I, in company with many others, have unwittingly extended its original implications to make it fit in with similar clinical entities which have been encountered in practice.—I am, etc.,

D. G. WILSON CLARKE.

Action of Penicillin

SIR.—Sir H. W. Florey, in his interesting article on penicillin, states that it is a "bacteriostatic." What does he mean by this term? Are we to understand that such an action, which takes place outside the body, is the one which takes place in the body, and is followed by recovery from the disorder? In other words, is penicillin to be used for the treatment of the "disease" or of the patient?—I am, etc.,

Swansea.

G. ARBOUR STEPHENS.

Infant Feeding

SIR.—Dr. Boucher (July 29, p. 160) calls attention to the prevalence of difficulties with infant feeding. Much unnecessary suffering could be prevented if cases of deficiency of breast milk were more promptly recognized and dealt with, and if mothers who cannot feed their infants entirely on breast milk were given adequate instructions about artificial feeding based on the methods recommended by Drs. Paterson and Smith in their book *Modern Methods of Feeding in Infancy and Childhood*. Some of the points on which these methods differ from others commonly in use are worth noting:

1. The quantity of the feed is calculated primarily according to the weight of the infant, larger babies getting larger feeds. Thus the needs of individual infants whose weights at birth or natural rates of growth differ from the average receive due consideration. If any difference is made between the quantity of feeds at the same age, it is the smaller babies who are given the larger feeds, on the assumption that all babies ought to have the same weight at a given age.

2. The composition of the feed is a simple milk, sugar, and water mixture, and for infants between 1 and 6 months old two-thirds of the total volume is made up of whole full-cream milk. Some methods of feeding give too low a concentration of milk and others too high.

3. It is made clear that sugar in appropriate amounts must be added to the feeds in order to get satisfactory results with artificial feeding. But the directions on tins of some brands of powdered milk mention the addition of sugar as optional. In giving a figure for the amount that may be added they fail to grade it according to the quantity of the feed, and the amount suggested is too little for all except the smallest feeds.

In addition to information about composition and quantity of feeds, a mother needs advice on the technique of bottle-feeding, including such matters as preparing a teat with a hole of the right size, and ensuring that the feed is reasonably near body temperature when it is being given.

There are some babies whose natural rates of growth are very considerably above the average, and who are only satisfied when receiving feeds that enable them to grow faster than the commonly accepted maximum rate. When such an infant is breast-fed and the mother has plenty of breast milk, and when the mother does not allow the natural process of feeding to be interfered with by undue fussing about scale and clock readings, then no difficulty arises. The large gains in weight are only discovered incidentally. The baby is contented. When, however, such an infant is being bottle-fed or if the mother has not sufficient milk to satisfy him, he may then appear as one of the cases of crying and fretfulness of unknown origin. There is nothing clinically wrong. According to accepted standards the gains in weight are satisfactory and the amounts of feeds are sufficient. Nevertheless the crying and fretfulness are due to the fact that he is not fully satisfied by the feeds. Increase them either in quantity or in concentration, or both, and he becomes satisfied. I think that if the existence of infants having these high growth rates were more generally recognized more cases of fretful infants and distressed mothers could be effectively remedied.—I am, etc.,

Leeds.

SYLVIA DICKINSON.

Post-operational Strain in the Navy

SIR.—I was interested in the article on post-operational strain by Surg. Capt. Curran and Surg. Lieut. Garmany (July 29, p. 144). I do not think, however, they have stressed sufficiently that it is a psychophysiological outrage when one is obliged to pass too quickly from a state of tension to one of relative

relaxation. The holiday neurosis, whereby the over-tense individual sustains an increase in anxiety during the first days of his vacation, is well known. Perhaps the authors would be interested to know that it is an absolute necessity in teaching patients the art of conscious relaxation to avoid relaxing them too soon. To aim at achieving too quickly a state of deep muscular relaxation is to promote feelings of anxiety and restlessness, which more than ever prevent the patient from relaxing. This slight criticism is not to say that one does not appreciate very much an outstanding article.—I am, etc.,

Bath.

A. GUIRDHAM.

SIR.—If one turns from the particular and clinical findings to the general and to trends in our cultural life, it is a fact that there has been for years an increasing tendency for the population—more noticeable in the large towns—to become dependent on artificial stimulation for their amusements and more passive in their attitude to leisure life in general. The machine age, with its damping effect on active handicrafts, has extended increasingly to the whole art of living, and the male—Surg. Capt. Curran's findings (July 29, p. 144) are limited to the sex—is becoming more sedentary and receptive in the way he spends his non-working life; he relies more and more on external stimulus to be provided and less and less on ideas arising within his own ego. Wartime increases this tendency, especially in the civilian population, since it is harder for the individual to come by the materials for his particular hobbies and to get the facilities for participation in sport and games. This sessile attitude toward life belongs to the ovum rather than to the spermatozoon, and it is, I think, largely contributory in Surg. Capt. Curran's findings.

It can truly be said that similar findings were commonly met with in behaviour difficulties in the male long before this war, and the interacting causes should be given serious consideration in any schemes for social improvement after the war. It may be that if the factors responsible for this reliance on commercial provision of stimulation at the expense of initiating his own libidinal drives continue, this sessile attitude may in the course of time become a permanent mutation in our male culture. Against this lack of ego-interest may be put the enormous increase in the hobby of gardening during the war.—I am, etc.,

London, N.W.5.

JOHN MACKWOOD.

Service Medicine

SIR.—The attack on certain aspects of Service medicine in your issue of April 1 provoked Air Cdre. Cade and Conybeare (April 22, p. 574) not only to paint an idealistic picture of medical organization in the Services but also to dismiss the anonymous writer as selfish or lazy and incompetent. I submit, Sir, that these R.A.F. consultants are making a serious mistake. Of the hundreds of temporary medical officers in all three Services to whose opinions I have listened since 1939 only one failed to deplore the anomalies and abuses of Service medicine, and this single exception admitted that he disliked clinical work.

Dr. Geoffrey Bourne has rightly remarked (*B.M.J.*, 1943, 1, 673) that administration should be the servant, not the master, of the public and its doctors. Service medicine is, on the contrary, ruled by officers who regard medicine as the slave of administration, and the consequences of this radical defect are fatal. Admittedly the skilled doctor is helpless without administrative machinery to provide essential supplies and transport. Such machinery can, however, be devised and operated for the most part by people whose training is far shorter than that required to graduate in medicine. Yet hundreds of medical officers, at a time when civilians cry out for more doctors, are engaged exclusively in so-called administration. I purposely say "so-called" because the word "administration" is often a pretentious euphemism for the process of signing redundant documents unread.

How, it may be asked, can these men reconcile their professional conscience to the performance of tasks within the capacity of a layman? Promotion is the answer. Simple administrative duties, easily mastered within a week or two, carry a higher rank than do most of the specialized clinical posts, although the latter cannot be efficiently filled except by people of long

training and experience. This subordination of clinical skill has placed overwhelming power in the hands of regular officers, who, in spite of being numerically negligible since the vast wartime expansion of all Services, yet hold nearly all the key positions. They are selected not only to command important hospitals and preside over medical boards but even to exercise control over clinical departments, thereby taking credit for work done by their Service juniors and professional betterers. Well-paid sinecures are also filled by ex-regular officers dug out of pensioned retirement.

Your anonymous correspondent will surely echo the hope expressed by those eminent Air Commodores, that he will remain out of a State Medical Service. Long may the public be spared the mockery of a whole-time salaried State Medical Service: but if this thing should come, then I venture to prophesy that the administrative lightweights, with their smattering of medical knowledge, will rise to the summit of the bureaucratic hierarchy; and the clinicians, who have perforce endured the brass-hatted administrators in time of war, will resume civilian life, only to be strangled by red tape.—I am, etc.,

TEMPORARY SERVING OFFICER.

Ultra-violet Light Treatment at Welfare Centres

SIR,—In the abridged notes of a lecture by Dr. Doyne Bell (July 29, p. 157) I fear a wrong impression may be implied of the use of ultra-violet rays in welfare practice. Dr. Doyne Bell condemns their use in the "prophylaxis of respiratory infection," whatever that may mean. Ultra-violet rays can be used in various other conditions in babies and young children with very satisfactory results, as I showed in an investigation carried out a number of years ago when I was M.O.H. at Middleton, Manchester. I go so far as to say that all child welfare centres should be equipped with U.V.R. lamps. When mothers generally report that their babies are sleeping better, thriving and putting on weight, and are more lively after a course of treatment, this is a sufficient guarantee of the usefulness of U.V.R. in clinic practice.—I am, etc.,

S. T. BEGGS.

Yeast in Furunculosis

SIR,—Among several present-day uses yeast still holds its own as an acknowledged remedy for boils and furuncles. In tablet form as the dried preparation it is of little or no use for the purpose; being, however, of substantial benefit if freshly skimmed from brewers' or distillers' wort and administered in its natural semi-fluid state, suitably suspended. This fresh yeast is exhibited in one-drachm doses in sweetened water thrice daily before meals. Or it may be given compressed as a bean-sized piece or as "yeast-cake" (1/4 to 1/2 oz. pro dos.), broken up and added to mineral water sweetened with sugar. Of the two, the semi-liquid yeast is the more active in therapy.

The pharmacological action of yeast was formerly believed due to its fermentative properties; but is it not more likely that its content of *Penicillium glaucum* contains the active chemotherapeutic principle that inhibits the *Staphylococcus aureus* and does the good? In view of the discovery that penicillin, prepared from the mould *Penicillium notatum*, is bacteriostatic to the *Staph. aureus* among other pyogenic organisms, does this not suggest an analogous action on the part of the *P. glaucum* of yeast? Here, perhaps, is a field for investigation. Yeast is given by mouth only, not by injection, or is it applied locally. It is possible that microscopic doses of *P. glaucum*, or its extract contained therein, are sufficient therapeutically; and that if wholly or partially destroyed by the hydrochloric acid of the gastric juice the stuff might be more potent given after alkalizing this; or, for that matter, might be most effective in the absence of HCl as in achlorhydria, constitutional or other. These considerations may account for yeast being unequal in its results.

Beer wort, by the way, even at room temperature, is a simple, useful test-tube medium for cultivating moulds and fungi by surface smear.—I am, etc.,

Bournemouth.

S. WATSON SMITH.

The Fly Menace

SIR,—I have just read Lieut.-Col. Gear's instructive paper (March 18, p. 383). He has pointed out how seriously the fly menace is viewed in the Army. He describes the work of Fly Control Unit consisting of five officers, several N.C.O. 200 to 300 British other ranks, and African pioneers. Needless to say, these personnel would not have been released for the duties had the work of eliminating flies not been deemed of urgent priority.

My mind goes back to an article, about a month previous by Dr. Shooter and Miss Waterworth (Feb. 19, p. 247). In it the following complacent statement occurs: "In September 1942, when flies abounded in this hospital. . . ." I suggest that the fly problem be tackled at its source. This would eliminate the need for papers on the transmissibility of haemolytic streptococcal infections by flies in hospitals. Let hospital administrators at home learn a lesson from the Army, and in their planning really give due consideration to this undoubted menace.—I am, etc.,

P. JACOBS,

Capt., I.M.S.

Mr. Prynne's Habits

SIR,—In your issue of July 15 (p. 91) the note on Pepys and alcoholism contains the remark: "Total abstainers in those days were exceptional. Such a one was Mr. Prynne." The statement does not agree with Aubrey's famous description of Prynne at his studies: "He wore a long quilt cap, which came 2 or 3, at least, inches over his eyes, which served him as an umbrella to defend his eyes from the light. About every 3 hours his man was to bring him a roll and a pottle of ale to refocillate his wasted spirits. So he studied and drank and munched some bread: and this maintained him till night; and then he made a good supper." I suspect that Prynne's objection was to the practice of drinking toasts and not to the practice of drinking liquor.

The late Sir Henry Maxwell Lyte pointed out to me, when I drew his attention to this passage some twenty years ago that the main purpose of Prynne's quilt cap was probably to conceal his mangled ears.—I am, etc.,

The University Library, Glasgow.

W. R. CUNNINGHAM.

Representation on Council of R.C.S.

SIR,—It is with great pleasure that I read of the invitation from the Royal College of Surgeons to the Association to nominate general practitioners, one of whom should serve as a co-opted member of the College Council (Supplement Aug. 5, p. 31). For 50 years the Society of Members R.C.S. has been trying to persuade the College Council to take such a step, as we have felt that the G.P.s should be represented on the Council, as they are by far the more numerous and contribute more to the College funds than any others.

There are many able men among the G.P.s who would be most worthy colleagues on the Council of the College, and would undoubtedly benefit that Council by knowledge they possess of "ordinary practice." This step on the part of the College is a welcome and graceful act.—I am, etc.,

PERCY B. SPURGIN,

President, Society of Members, R.C.S.

The Alvarenga Prize for 1944 has been awarded by the College of Physicians of Philadelphia to Dr. Gervase J. Connor, Department of Surgery, Yale University School of Medicine, New Haven, Connecticut, for a paper entitled "Anterior Cerebellar Function: An Analytical Study in Functional Localization in the Cerebellum in Dog and Monkey." This prize was established by the will of Pedro Francisco da Costa Alvarenga of Lisbon, Portugal, an Associate Fellow of the College of Physicians, "to be awarded annually by the College of Physicians on each anniversary of the death of the testator, July 14, 1883, to the author of the best memorial upon any branch of medicine which may be deemed worthy of the prize." Dr. Connor's paper will be published in the *Transactions and Studies of the College of Physicians*, December, 1944.

Obituary

ALEXANDER PRIMROSE, C.B., F.R.C.S.

We regret to announce the death, at the age of 82, of Alexander Primrose, formerly dean of the Faculty of Medicine of Toronto University. Primrose, who was born in Nova Scotia, studied medicine at Edinburgh, qualifying M.B., C.M. in 1886, and after a period at the Middlesex Hospital returned to Canada to practise in Toronto. In 1896 he was appointed professor of anatomy at Toronto, a post he held until 1907. Dr. Primrose went over-seas in 1915 as surgeon with No. 4 Canadian General Hospital, and later served in Salonika, returning to England in 1916 as consulting surgeon to the Canadian Forces. He was mentioned in dispatches, and in 1918 received the C.B. When he returned to Canada at the end of 1918 he was appointed professor of clinical surgery at Toronto. He held his post until 1931, and for a great part of that time (from 1920 to 1932) was also dean of the Faculty of Medicine. In 1925 he was made a Fellow of the Royal College of Surgeons, and among a number of offices he held were president of the Canadian Medical Association, of the American Surgical Association, and of the Toronto Medical Society.

Prof. GREY TURNER writes:

For many years Alexander Primrose was an outstanding figure in Canadian medical life, and especially in connexion with the University of Toronto, where he originally lectured in anatomy, and for years afterwards occupied the position of professor of clinical surgery and of dean. I remember so well the prominent part he played at the time of the meeting of the British Medical Association in that city in 1906. From then onwards he continued to be most active both in surgery and in university affairs. He was interested in the wider field of medicine and in medical education, and was always anxious to keep in touch with the work going on in what he always referred to as the old country, which he loved to visit whenever opportunity arose. It gave him immense pleasure to be elected a Fellow of the College of Surgeons as a member of twenty years' standing in 1925, and he was particularly proud to be asked to represent the College thereafter in connexion with functions in his own country. Primrose was accepted as an outstanding representative of Canadian surgery by American surgeons; he was an honorary Fellow of the American College and he had held high office in several of their societies. But though his professional work naturally slackened off very considerably in recent years, he contributed from his experience at the meetings of societies and to the journals, and he gave a very interesting address as president of the American Surgical Association in 1931. He was of a very kindly disposition and always anxious to be helpful, and his wide knowledge of men and affairs encouraged application to him for guidance. Primrose was the sort of man to whom colleagues naturally turned for advice, and he seemed especially cut out for the position of doyen, a seniority which he occupied gracefully for several years.

By the death on July 10 of Dr. A. E. KIDD, of Dundee, the Scottish School Medical Service has lost one of its pioneers. Alexander Edward Kidd studied medicine at Dundee, at Edinburgh University, and at University College, London, graduating M.B., C.M. at Edinburgh in 1894. In 1901 he also took his D.P.H. at St. Andrews University. "J. H." writes: Dr. Kidd had many interests, but the main one was his life-work—the health and well-being of the youngsters of Dundee. For over a quarter of a century he was in charge of pre-school and school medical administration in Dundee. As a member of the Territorial Army he saw service in the last war, and was in command of stationary and general hospitals in Serbia after being in France with the 3rd Highland Field Ambulance of the famous 51st Division. His work was recognized and honoured by the British, Greek, and Serbian Governments. He received the O.B.E. and was mentioned five times in dispatches. Dr. Kidd retired from the School Medical Service in 1937 on attaining the age limit, but on the outbreak of war he took charge of Civil Defence casualty work and first-aid posts in Dundee. This post he held until failing health compelled him to give it up. In recognition of his services in the city he was made a Deputy

Lieutenant in 1943—an honour which was well deserved and which he thoroughly appreciated. He was one of the founder members of the Association of School Medical Officers of Scotland. Indeed, if my memory is correct, he was its first honorary secretary. In due course he became president, and his period of office culminated in a successful conference in Edinburgh in the early 'twenties. It was during this time that my friendship with him deepened and I learned to appreciate in proper degree his sound professional knowledge, his powers of organization, and his downright common sense. He was a most delightful companion to adults and children alike. He would have celebrated his jubilee in medicine if he had survived until Aug. 1: it was on that date in 1894 that he was "capped" at Edinburgh University. He leaves behind among his colleagues very happy and unfading memories.

Medical Notes in Parliament

Distribution and Use of Penicillin

In an answer, on Aug. 3, to Mr. Linstead Mr. WILLINK said that up to the present all official supplies of penicillin, apart from a small quantity used for clinical trials, had been reserved for the Services and air-raid casualties. Production was, however, increasing to such an extent that it would shortly be possible to make some penicillin available for general civilian use. It was expected that some time next year the supplies would be sufficient to meet all requirements. During the transitional period it was essential to restrict the use of penicillin to cases in which it was likely to save life or to be the only available means of effecting recovery from grave illness. It had been arranged to issue the available supplies to university medical schools for use in their teaching hospitals and other hospitals approved by them in their areas. For the time being the issue would be made free of charge. The conditions for which penicillin should be used would be indicated in an official memorandum. Suitable cases would be admitted to the hospitals concerned. It would not be possible at present to make penicillin available to private practitioners.

Preparation of penicillin required the highest possible technical control to prevent the marketing of inferior and possibly dangerous preparations. For the present all supplies were obtained from the Ministry of Supply, who satisfied themselves through their staff of competent inspectors as to the quality of the penicillin before issue. Regulations had also been prepared for prohibiting the manufacture of penicillin for sale except in accordance with a licence issued under the Therapeutic Substances Act, and in conformity with prescribed conditions, including tests for strength, quality, and purity.

Ministry of Health's Social Survey

Brig.-Gen. CLIFTON BROWN on Aug. 3 asked Mr. WILLINK why inquiries had been made of people living in the Hungerford district about their health and past illnesses without consulting their local doctor who attended them. He asked whether the Minister would stop these proceedings in future. Mr. WILLINK said the visitor was a representative of the War-time Social Survey of the Ministry of Information, which since January had been carrying out, on behalf of his Department, a sampling inquiry in England and Wales. The object was to assess the amount of ill-health, including minor illness, which did not necessarily come under treatment by a doctor and was not otherwise recorded. This survey was providing information essential to a proper understanding of health statistics which could not be attained in any other way. He would not agree to stop the survey, but any information given by people in response to it was entirely voluntary. Experience had shown that practically everyone approached had been very willing to be helpful.

On the same day Sir E. GRAHAM-LITTLE asked a similar question and was referred to the above reply.

Evacuation: Position of Invalids

Mr. WILLINK, answering Mr. Pritt on Aug. 3, said arrangements were proceeding for the removal from danger areas of a number of permanent invalids already in institutional accommodation. For other infirm and invalid persons the Government Evacuation Scheme provided for the issue of travel warrants and billeting certificates if they could arrange for their own accommodation in safer areas. With the resources available he could not hold out hope that it would be possible to undertake the organized evacuation of all permanent invalids from areas at present subject to bombing.

Jamaican Medical Service

Ten doctors, Col. STANLEY stated on Aug. 2, have resigned from the Jamaican Medical Service during the last three years. One of these doctors resigned when on leave in the United Kingdom, where her husband was posted on military duty; one returned to the United States, of which he was a citizen; one, a Dutch refugee, proceeded to Curaçao at the request of the Netherlands Government; one resigned without giving any reason; and one has since rejoined the medical service. In general, said Col. Stanley, the reasons put forward for resignation were inadequate travelling and subsistence allowances, differences with the senior medical officer, protests against transfers, and lack of time for private practice. The salaries of medical officers were substantially increased as from April 1, 1943. Newly appointed officers who previously received a fixed salary of £400 per annum now get £500 per annum, rising to £600 per annum plus a sum of £300 per annum in lieu of private practice where that is not available or permitted.

The Government's New Houses

In the House of Commons on Aug. 1 Mr. WILLINK moved the second reading of the Housing (Temporary Accommodation) Bill. He referred to the urgent need to provide family housing during the period at the end of the war before permanent houses could be provided, and said that this consideration pointed to a type of building capable of production away from the site—a type of building, so far as possible, factory-made. A scheme was required to meet urgent needs as quickly as possible, and that pointed to standardization. A start would be made in time of war, and there was reason to think that something of the order of 100,000 of these houses—or bungalows, as he preferred to call them—could be produced within one year of going into production. Economy of labour, material, and time could be achieved by accepting some reduction in normal standards, and primarily in the standard of total size. Under most building by-laws, the normal minimum height of rooms was 8 ft., and the height of the rooms in the bungalow would be 7 ft. 6 in. The ventilation would be so arranged, however, that there would be no ground for anxiety and there would be an economy of material.

The actual area of the bungalow, excluding the detached outdoor shed, would be 616 sq. ft. compared with the range of 800 to 900 sq. ft. contemplated for the normal permanent family house. There would be no staircase, and there would be two bedrooms instead of three. There would be a living room, kitchen, two bedrooms, bathroom, separate w.c., and a detached outdoor shed. The Minister of Works had obtained a wealth of advice on this matter. He had used the full resources of the Department of Scientific and Industrial Research, and had even consulted the Medical Research Council. The materials and method of construction had been very carefully considered. Heat and cold, condensation, noise, liability to wear and tear, and cost of upkeep had been considered, and it was intended to produce a simple manual for tenants to help them in management and upkeep. This bungalow was probably more scientifically correct than any house had ever been. He could only hope it would be correspondingly comfortable. Special attention had been given to cupboard space, and there would be a refrigerator in the kitchen. It was estimated that the cost would be about £600 a bungalow, including transport and erection. The Government was considering more than one type of these bungalows.

Miss LLOYD GEORGE said that the new bungalows were meant for small families, but she hoped the families would not remain small. What, she asked, was to happen as the families grew? Mr. SILKIN said that these houses would not stand up to rough weather: a height of 7 ft. 6 in. was all right in the country, but in towns it was bad. In London the minimum height was 8 ft. 6 in. There was also a real danger of warping with steel houses. There was grave danger of vermin in London and many other large towns. He was advised on high authority that these houses were peculiarly susceptible to vermin. Mr. WILLINK said it was to that matter that he had referred, more delicately, when he mentioned consultation with the Medical Research Council.

The debate was adjourned.

Diseases Attributable to War Service

During a debate on pensions and grants on Aug. 3 Mr. DOUGLAS directed attention to the refusals of pensions in the case of men who had suffered from certain constitutional diseases or from diseases of which the cause was unknown. He asserted that there was a policy of excluding completely categories of cases and refusing to give them the benefits which the Royal Warrant provided. The Ministry threw back on the

claimant the onus of proof which the Royal Warrant intended to remove. An amendment made to the Warrant on Oct. 4, 1943, had provided that where the injury or disease which led to discharge or death was not noted in the medical reports made on the commencement of war service, a certificate should be given as a matter of right unless the evidence showed that the conditions were not complied with. It further provided that the benefit of any doubt should go to the claimant. The Ministry had ignored these provisions and had said there was short list of diseases which could not be attributed to war service. He (Mr. Douglas) asked Sir Walter Womersley to recognize that a consensus of medical opinion was not evidence and that it was not permissible to interpret the Royal Warrant by reference to statements by somebody, however eminent. The Ministry must interpret the Warrant by what was contained in it.

Sir WALTER WOMERSLEY replied that he was fortified by the best legal opinion. The Ministry did not "turn down" every case of a disease which the consensus of medical opinion had declared was not due to war service. Account was taken of aggravation by wrong diagnosis or by wrong treatment in hospital. The Ministry was guided by medical opinion on the diseases which could not be attributed to war service. The entitlement practice was based on the advice of experts nominated by the Royal Colleges of Physicians and Surgeons and the Medical Research Council. This procedure had been followed during the war and extended by the holding of conferences with eminent specialists on new problems as they arose. Cancer was one disease scheduled by consensus of medical opinion as not due to the war. Men whose disability was not due to war service or aggravated thereby came under the ordinary social services and got as good treatment as did the ordinary civilian.

Skin Sores following Malarial Therapy.—Replying on Aug. 1 to Mr. Robertson, Sir JAMES GRIGG said Army medical authorities were familiar with the cases of soldiers in India who, after prolonged malarial preventive treatment with quinine, mepracine, and other drugs, with the effect of the climate and insect pests, developed skin sores. Arrangements existed for treating these cases in India and also for transferring from India such men as became medically unfit to serve there. Most of the men who had done five years' service over-seas had by now left for the United Kingdom.

Notes in Brief

Giving on Aug. 1 instances of German looting and vandalism in Italy, Sir JAMES GRIGG recorded that the Germans took the entire library of medical books from the Biblioteca Comunale at Vasto.

In his survey of the war situation, which Mr. Churchill made on Aug. 2, he said the efficiency of the hospitals with our large armies in many varied theatres reflected high credit upon the War Office.

Forty-one cases of smallpox, two fatal, have been reported among British troops in India since the first landing.

Medical News

Mr. Gordon Harker, the actor, will broadcast an appeal for the Royal Westminster Ophthalmic Hospital, High Holborn, in "The Week's Good Cause" on Sunday, Aug. 20.

The allowance of dried bananas to children with steatorrhoea (including cases of coeliac disease while they have steatorrhoea) will in future be 7 lb. a month instead of 14 lb. Applications accompanied by a detailed medical certificate, should be made to the local Food Office in the usual way.

The prize distribution and conversazione of the Royal Dental Hospital will be held at the hospital, 32, Leicester Square, W.C.2 on Oct. 7 at 3 p.m., when Sir Alfred Webb-Johnson will preside. Past students are asked to accept this as an invitation to attend.

The telephone number of the National Hospital for Nervous Diseases, Queen Square, London, W.C.1, has been changed to Terminus 7721 (7 lines).

The Trustees of the Leverhulme Research Fellowships have approved the award of a grant to A. J. Lea, M.B., Ch.B., for research on the association of colour with other characters. Applications for forms and further information about the Fellowships may be obtained from the Secretary, Leverhulme Research Fellowships, Unilever House, Blackfriars, E.C.4.

The Professional Classes Aid Council (20, Campden Hill Square, London, W.8) exists for the relief of distress among the professional classes and others considered suitable. Lord Dawson of Penn is a patron, and among the bodies represented on the council are the Royal College of Physicians, the British Medical Association, and the Royal Medical Benevolent Fund. The annual report for 1943-4 briefly recounts what the Council has done during the year and includes a financial statement.

EPIDEMIOLOGICAL NOTES

Discussion of Table

England and Wales during the week notifications of acute pneumonia were 76 higher than last week, and those of scarlet fever 61 higher, but measles notifications fell by 49.

The rise in scarlet fever notifications was due mainly to an increase of 59 in Yorks West Riding, and of 24 in Glamorgan. Lancashire showed a rise of 47 in the incidence of acute pneumonia, and Sussex recorded 39 more cases of whooping-cough than last week. The largest decreases in the notifications of measles, were in Lancashire and Northumberland with 68 and 42 cases respectively fewer than last week, in Devonshire notifications went up by 31, and in Dorsetshire by 29.

Notifications of dysentery, 149 in all, were 2 fewer than last week. The largest returns were Lancashire 22, Dorsetshire 17, Essex 16, London 15, Yorks West Riding 10.

In Scotland notifications of diphtheria fell by 21, and of scarlet fever by 31. The 86 cases of dysentery were 5 fewer than last week's total; the highest returns were Edinburgh 36, Glasgow 17, and Lanark County 18.

In Eire the incidence of measles fell by 49. Over half of the total notifications were from two areas: Clare, Ennis U.D. 32, and Roscommon, Roscommon R.D. 20. The notifications of diphtheria remained at the relatively high level of the preceding fortnight.

Tuberculosis in Wales

At the annual meeting of the Welsh National Memorial Association it was stated that the tuberculosis death rate in Wales was lower than in any pre-war year. 890 patients were awaiting admission to hospital—the highest number in the association's history.

Quarterly Returns for England and Wales

In the first quarter of 1944 the birth rate was 17.9 per 1,000, the highest rate for a March quarter since 1926. In the first quarter of 1943 the birth rate was 16.9, and the average for the five preceding first quarters was 15.0. Infant mortality was 58 per 1,000 live births, and 14 below the average of the ten preceding first quarters. The general death rate was 14.2 per 1,000, compared with 13.5 for the first quarter of 1943 and the average rate of 16.2 for the five March quarters before 1943. The marriage rate of 12.1 per 1,000 was the lowest rate for a first quarter since 1939.

The deaths in England and Wales for 1943 show that diphtheria mortality was the lowest on record. There were 1,368 deaths from this disease, compared with 1,827 in 1942 and 2,641 in 1941. Deaths from respiratory tuberculosis increased by 552 for males, but decreased by 202 for females.

Quarterly Returns for Northern Ireland

The birth rate during the March quarter was 23.3 per 1,000, which is 2.6 above the average of the five preceding first quarters. Infant mortality was 85 per 1,000 registered births, 10 below the five-years average. The general death rate was 15.6 compared with 17.4 for the average of the five preceding March quarters. Deaths from pulmonary tuberculosis numbered 233 and from other forms of tuberculosis 80, the former being 40 below and the latter 5 above the five-years average. Deaths from whooping cough and infantile diarrhoea were 6 and 23 above the average while deaths from influenza were 92 below. Diphtheria accounted for 26, the same as the five-years average.

Registrar-General's Annual Report for Northern Ireland, 1940

The births registered during the year were equivalent to a rate of 19.6 per 1,000. The infant mortality was 86 per 1,000 registered births, 16 higher than in 1939. The maternal mortality rate was 4.22 per 1,000 births, an increase of 0.42 on the rate of the preceding year. A general death rate of 14.6 per 1,000 was 1.1 above that for 1939. The downward trend of tuberculosis mortality was arrested by a rise of 14 to 98 per 100,000. Deaths from cerebrospinal fever increased from 17 in 1939 to 58 in 1940. Diarrhoea under 2 years of age was responsible for 387 deaths, 110 more than in 1939.

Week Ending August 5

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,410, whooping cough 1,768, diphtheria 471, measles 2,154, acute pneumonia 376, dysentery 139, paratyphoid 7, typhoid 15.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended July 29.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included) (b) London (administrative county) (c) Scotland (d) Eire (e) Northern Ireland

Figures of Births and Deaths, and of are for: (a) The 126 great towns (b) London (administrative county) The 13 principal towns in Eire (c) T

A dash — denotes no cases, a blank space denotes disease not notifiable or no return available.

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

The Services

Col N. Cantlie, M.C., late R.A.M.C., has been appointed D.D.M.S. of a Command, and has been granted the acting rank of Major-Gen.

Air Cdre T. C. St. C. Morton, O.B.E., has been appointed an Honorary Physician to the King in succession to Air Cdre H. L. Burton, who has vacated the appointment on retirement from the R.A.F.

Capt C. Sonick, I.A.M.S., has been awarded the M.C. in recognition of gallant and distinguished services in Italy, and Capt. A. G. Hewer, R.A.M.C., in recognition of gallant and distinguished services in the field.

Temp Surg Lieut A. H. Zuckerman, R.N.V.R., has been commended for skill and endurance in services to injured survivors when a merchant ship was wrecked on a desolate part of the coast of Scotland.

CASUALTIES IN THE MEDICAL SERVICES

Wounded—War Subs Capt. G. M. Clark, A. B. Hill, G. C. Kennedy, S. M. G. McGuffie, D. W. Moynagh, A. G. Richards, D. N. Thornton, E. N. Whitley, R.A.M.C.

Killed in action in Normandy—Capt. C. R. Veall and A. D. Fisk, R.A.M.C.

Reported missing at sea, now presumed killed in action—Major E. B. Rotherham, R.A.M.C.

Missing, believed prisoner of war—Major J. S. Darling, R.A.M.C.

Killed accidentally while on duty—Capt. S. Conway, R.A.M.C.

Died—Major C. F. Rainer, R.A.M.C.

Universities and Colleges

UNIVERSITY OF OXFORD

In a Congregation held on July 29 the following degrees were conferred:

B.M., B.Ch.—J. C. Chartres, F.R.M. Elgood, H. C. Nohl, Nancy D. Cox
1 In absentia

UNIVERSITY OF LONDON

The following candidates have been approved at the examination indicated:

M.D.—Branch I (Medicine) G. D. Daruvala, P. Forgacs, J. W. Paulley
Branch III (Psychological Medicine) W. E. W. Bridger, Branch VI (Tropical Medicine) A. C. Howard

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At an ordinary meeting of the Council held on Aug. 3, with Sir Alfred Webb-Johnson, President, in the chair, it was decided to invite the following representatives of the branches of practice indicated to attend meetings of the Council during the ensuing collegiate year:

Dr. H. Guy Dain (general practice), Mr. V. E. Negus (otolaryngology), Dr. A. D. Marston (anaesthetics), Mr. George Black (ophthalmology), Mr. G. F. Stebbing (radiology), Prof. R. V. Bradlaw (dental surgery).

It was decided to recognize the posts of fourth house-surgeon at the East Suffolk and Ipswich Hospital and of resident surgical officer and casualty officer at the City General Hospital, Leicester, for the six-months surgical practice required of candidates for the Final Fellowship examination. Sir Frank Colyer was reappointed Honorary Curator of the Odontological Collection of the Museum for a further year. Mr. H. S. Souttar was appointed the representative of the College on the Scientific Advisory Committee of the Radium Institute and Mount Vernon Hospital.

Diplomas

Diplomas of Membership were granted, jointly with the Royal College of Physicians of London, to the candidates whose names appear in the report of the meeting of the Royal College of Physicians of London in the *Journal* of Aug. 12 (p. 227). Diplomas were granted, jointly with the Royal College of Physicians of London, as follows:

DIPLOMA IN OPHTHALMIC MEDICINE AND SURGERY—J. A. Chivers, Philomena M. Guinan, W. Harris, H. G. W. Hoare, M. Klein, L. Lurie, S. J. H. Miller, M. C. Mundie, V. G. Patel, E. C. Richardson, R. H. Rushton, W. Shortus, G. L. Simmons, R. Spink, Mabel E. Stewart, G. F. Wright.

DIPLOMA IN MEDICAL RADIOLOGY—K. E. Barlow, R. J. Carr, F. H. Cross, Kathleen M. Packett, G. Steiner.

DIPLOMA IN PHYSICAL MEDICINE—F. S. Cooksey.

Before the meeting of the Council the Blane Medal was presented by Surg. Vice-Admiral Sir Sheldon Dudley, Medical Director-General of the Royal Navy, to Surg. Cmdr. W. A. Hopkins, O.B.E., M.D., R.N., in the presence of Lord Moran, President of the Royal College of Physicians, and the President and Council of the Royal College of Surgeons.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to: EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE EUSTON 2111. TELEGRAMS: *Articulate Westcent London*. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publisher, Manager, B.M.A. House, Tavistock Square, W.C.1 on receipt of proof. Authors over seas should indicate on MSS. if reprints are required as proof are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE EUSTON 2111. TELEGRAMS: *Articulate Westcent London*.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association, TELEPHONE EUSTON 2111. TELEGRAMS: *Medicent Westcent London*.

B.M.A. SCOTTISH OFFICE: 7, Drumshugh Gardens, Edinburgh.

ANY QUESTIONS?

Injections for Arthritis

Q.—Can you give me any information about the injection solutions into painful joints for the relief of arthritis?

A.—An article recently appeared (*Lancet*, 1944, 1, 563) on the injection of joints in rheumatoid arthritis with acid potassium phosphoglycerate. Good results being claimed in a large series of cases. The method must, nevertheless, be considered to be in the experimental stage, and further controlled observations will be required before it can be regarded as a safe and effective method of treatment. It would be desirable at the present stage that it should be tried only in hospital, where rigid antisepsis and careful nursing and observation would be possible.

Chloride Content of Blood in Drowning

Q.—In cases of drowning, what is the medico-legal significance of alterations in the chloride content of blood and pleural fluid?

A.—In cases of drowning water tends to enter the respiratory tract just before death, and it has been found that if drowning takes place in fresh water there is a tendency for the percentage of chlorides to be lowered in the blood generally, and, further, the percentage in the left heart is lower than that in the right heart. When drowning takes place in salt water there is a tendency to increase the chloride of the blood generally, and in particular the blood of the left heart has a higher content than the blood in the right. After drowning in sea water the magnesium is increased in the blood generally, and the amount in the left heart is greater than that in the right. Examination of the blood for chlorides and magnesium in both sides of the heart, is therefore helpful in arriving at an opinion as to whether in a body found in water death was actual due to drowning. These changes are most significant in bodies recovered before putrefaction is advanced. It is obvious that the changes will depend upon the rapidity of death after submersion and particularly upon the length of time the circulation continues after water has been admitted to the lungs—that is, after consciousness has been lost. Obviously the greater length of time between the one phenomenon and the other, the more equal would be the dispersion of chlorides between the two sides of the heart.

"Safe" Period

Q.—A healthy young woman has borne three children in 5 years. Before marriage menstruation occurred regularly every 30-31 days. Menstruation began again 6 weeks after each confinement and now occurs at intervals of 36 to 42 days. Is it possible (a) to restore previous regularity—e.g., by the use of stilboestrol or progestin—and (b) to advise on a "safe period," however short? The patient's sister, whose periods have always occurred regularly every 21 days, has also sought advice on a "safe period." Would the regular timing of the vaginal temperature before rising provide a useful indication of the date of ovulation in either case, and, if so, could the date be related to a possible "safe period"? Both patients are intelligent women and decline contraceptives on ethical grounds.

A.—Some alteration in the menstrual cycle after pregnancy is not uncommon, and unless there is other evidence of endocrine disturbance, such as gross alteration in weight, spontaneous cessation of the rhythm is to be expected. Neither stilboestrol nor progestin is indicated, and although thyroxine, gr. 1/2 to 1 each night regularly for two to three months, appears to help to regulate the cycle at times, there is much to be said for adopting an expectant attitude in this case.

Ovulation occurs approximately 14 days before the onset of the next menses, so in a 21-day cycle it is soon after the last period ceases. The only reasonably "safe period" is therefore the 7-14 days preceding menstruation. With a cycle so irregular, as in the first case, it is difficult to predict the time of ovulation, especially

as there is a possibility of spontaneous alteration at any time. With the exception, perhaps, of the two or three days immediately after menstruation I should therefore hesitate to advise any time as being safe.

Observations on temperature changes during the menstrual cycle have mostly been based on rectal recordings, but the vaginal temperature probably tallies closely. There is a general agreement that the highest temperatures are registered during the premenstrual phase, with a fall at the onset of the flow. It has also been claimed that on the day of ovulation there is a fall in temperature (Zuck, T. T., *Amer J Obstet Gynec*, 1938, 36, 998), but this is not confirmed by all workers. In any case the range of variation is so small and observations need to be so accurate and carefully controlled that this cannot be recommended as a practical means of assessing the time of ovulation. Both patients, however, if observant, might be able to get some indication by watching for slight lower abdominal discomfort and for mucoid vaginal discharge, sometimes blood-stained, either of which may appear for one to three days round about the time of ovulation.

Function of Spleen

Q.—*Apart from its activity in blood formation and destruction, what is the function of the spleen? Is there any evidence of an internal secretion, and could you recommend a recent monograph on the spleen in particular or the reticulo-endothelial system in general?*

A.—The spleen acts as a reservoir for blood, though the significance of this function varies in different species and is probably minimal in man. The spleen also plays an important part in infection and immunity. This is very prettily shown in the rat, which frequently has a latent *Bartonella* infection but is liable to succumb to the infection if the spleen is removed. There is some relation between the lymphatic tissue of the spleen and the absorption of protein. Extracts of the spleen have been said to reduce the platelet count and the red cells, and they have been used for the latter purpose in polycythaemia, but the effects have not been generally confirmed. Spleen has also been used as a treatment for tuberculosis. It is doubtful whether the spleen has an internal secretion in the ordinary sense of the term. Most of the functions of the spleen can apparently be taken over by other tissues, but the red cells show abnormal nuclear remnants or Howell-Jolly bodies indefinitely after splenectomy. Recent monographs on the spleen are *Physiologie der Milz* by E. Lauda, Berlin (1933), and *The Spleen and Resistance* by E. Perla and J. Marmorston, Baltimore and London (1936), the latter is probably the most suitable book for the present inquirer. Two attractive French books, both published by Masson of Paris, are *La Rate, Organe Reservoir*, by Leon Binet (1930), and *L'Exploration Fonctionnelle de la Rate*, by Ed. Benhamou (1933), neither, however, deals at length with questions of an internal secretion or immunity. The best recent account of the reticulo-endothelial system is probably the 300 page review by R. H. Jaffe in Hal Downey's *Handbook of Haematology* vol. II, London, 1938.

Isolation of Scarlet Fever

Q.—*What is considered the minimum quarantine for uncomplicated cases of mild scarlet fever treated with serum?*

A.—The inquirer doubtless means minimum period of isolation. Current practice in fever hospitals is to release adults towards the end of the third week and children during the fourth week from the onset. It is known that about 50% of patients harbour haemolytic streptococci in varying numbers on release from hospital, but only some 1% to 4% (the higher rates in the winter months) give rise to new ('return') cases. Patients nursed singly can usually be discharged somewhat earlier because reinfection does not occur, as it frequently does in a hospital ward accommodating 20 patients mingling more or less freely when convalescent. If two negative consecutive swabs are obtained the patient may be released still earlier, the nose and nasopharynx being examined as well as the fauces or tonsils. There is available neither a simple test to determine virulence of the streptococcus nor a reliable criterion to determine how many organisms are likely to lead to infection.

Muscular Twitching before Sleep

Q.—*A man of 35 states that shortly before going to sleep his body gives a violent convulsive movement. This is frequently repeated and occasionally occurs during his sleep. He is a normal, healthy man, mentally stable, and free from any evidence of organic nervous disease. I have heard of, and experienced, mild and sometimes generalized muscular twitches when the body is relaxing, but I have never seen or crossed a case where they are so regular, persistent, and violent. Are any further investigations indicated?*

A.—A solitary muscle twitching of an involuntary nature which occurs as a person is going off to sleep is quite normal. Its frequency and the number of muscles involved vary greatly from person to person. Everyone has experienced a sudden, quick jerk of the

leg or arm, and the usual story is that this occurs in any limb a few times a year. It has been observed that people who have very frequent twitching of this sort are more often subject to epileptic fits than are others, but this does not mean that this particular patient either is epileptic or is going to develop fits. It might be interesting, however, to inquire whether he has epilepsy in his family.

Non-tropical Elephantiasis

Q.—*A middle aged woman has severe non-tropical elephantiasis. Is there any operation which would offer a possibility of relief or cure?*

A.—It is assumed that the condition affects one leg, and that there is no discoverable vascular obstruction in the groin, pelvis, or abdomen. In such circumstances it may be possible in a favourable case to place a full-thickness (pedicle) skin graft with its lymphatics as a bridge between the "oedematous" thigh and the normal abdominal skin. The graft should be placed so that the lymph stream through it may flow in the same direction as it followed when the skin was in its original position. When this method cannot be adopted, the alternative is to excise the thickened subcutaneous tissue with broad longitudinal strips of the deep fascia, and then either to trim the skin so that when it is sutured it fits tightly over the exposed muscles, or to remove the skin completely and make good the defect with split skin grafts placed directly on the muscle or fascia. This procedure must be carried out in multiple stages: one side of the limb being done at a time. Should this fail, amputation may be inevitable.

After-treatment of Acute Nephritis

Q.—*Two children (5 and 6) had a sharp attack, three months ago, and now, although the blood pressure and blood chemistry are back to normal, each continues to pass albumin in the urine, varying from a faint trace to 1 part per 1,000 (Esbach). They are kept in bed, and most textbooks agree that bed rest is advisable until there is no further reduction of albuminuria. However, no definite progress is being shown as on some days the protein cloud is as heavy as it was two months ago. Is the object of bed rest merely to avoid draughts and if so are not the risks of a chill less in a well-clothed child up and about than in one who feeling perfectly fit, is constantly in and out of bed dressed only in a flannel bed jacket, despite all the efforts of the nursing staff to keep him in bed?*

A.—Assuming that by "a sharp attack of acute nephritis" the questioner means nephritis of abrupt onset associated with haematuria (Type I nephritis), often a sequel of tonsillitis, two points should decide whether further bed rest is necessary or not. A urine deposit should be examined for red blood cells. If no more than a few are seen, the patient should be allowed up and the ultimate prognosis should be good. Secondly, the presence of orthostatic albuminuria should be excluded. This can be done by examining the early morning specimen of urine. Specimens passed later in the day may contain additional "orthostatic albumin" if the child has been sitting up, and more so if walking about, the maximum amount occurring after 2 to 3 hours. Therefore, if there is no excess of red blood cells in the urine deposit, and if the early morning specimens contain no more than a faint trace of albumin—the other clinical features being as described—complete recovery is to be expected and the patient should be allowed up. Convalescence should be managed in the usual way.

Toxaemia persisting after Parturition

Q.—*In most cases of toxaemia of pregnancy the condition clears up after parturition. What is the correct treatment for those cases where the blood pressure reading remains abnormally high and a variable degree of albuminuria persists? In the type I have in mind there are no casts or blood cells in the urine and primigravidae can behave so as well as multiparae.*

A.—The persistence of an abnormally high blood-pressure reading is common after a toxæmic pregnancy. Prof. Browne and Miss Dodds (*J. Obstet. Gynaec. Brit. Emp.*, 1939, 46, 443) found a persistent hypertension in about 40% of patients who had suffered from pre-eclamptic toxæmia. Recent work by Theobald, and in the United States, suggests that this hypertension is probably not caused by the toxæmia, but that such patients are potential hypertensives and that their blood pressure would rise with age even if they had never been pregnant. The American workers claim to have shown that hypertension is an extremely common condition and that, in fact, 40% of adults are actually or potentially hypertensive. Hypertension following a toxæmic pregnancy does not call for any treatment and is important mainly for its possible effect on subsequent pregnancies, since Prof. Browne and Miss Dodds (*J. Obstet. Gynaec. Brit. Emp.*, 1942, 49, 1) have also shown that in cases where the blood pressure exceeds 150/100 before pregnancy, or in the first 20 weeks, in only 30% does the foetus survive.

It is known that albuminuria may take a long time to clear up. A case has been recorded where albuminuria persisted for two years.

after confinement and then cleared up completely. No treatment is required.

The persistence of hypertension and albuminuria together for a long time after childbirth is suggestive of either chronic nephritis or malignant hypertension, though neither of these is likely in the absence of casts. In such cases, however, examination of the fundus oculi and renal function tests should be carried out.

D.D.T.

Q.—I understand the powder used so successfully in Naples to rid both persons and rooms of lice is known as D.D.T., which chemically is dichlor-diphenyl-trichlorethane. What is the graphic formula for this?

A.—The formula is:

The drug is used diluted with an inert carrier, not "neat."

An account of D.D.T. was given in a leading article in last week's *Journal*.

INCOME TAX

P.A.Y.E. on Fees for Unaccompanied Evacuated Children

"S." writes: An inspector of taxes claims that, as regards an M.O.H. not in private practice, these fees cannot be treated as part of general earnings assessable under Schedule D, and consequently tax should be deducted under "pay as you earn."

* For tax to be so deductible the earnings must be emoluments assessable under Schedule E—i.e., derived from holding an office or employment of profit. As we understand the position doctors undertaking this work are not employed by the local Medical War Committee Bureau—i.e., the relationship of master and servant is not created by the arrangements made—and if so the fees are assessable not under Schedule E but under Schedule D, as professional profits. It is suggested that this view be put to the inspector of taxes concerned.

Retirement

R. C. inquires: "Supposing I retire at the end of next March, when do I pay my last instalment of income tax on my practice?"

* The last year of assessment will be that ending April 5, 1945, the tax payable being due in two instalments on Jan. 1 and July 1, 1945. If, however, "cessation" is claimed, the last year is liable to be assessed on the basis of the earnings of the current year, in which case some supplementary amount of tax may become payable later.

Hospital Appointment: "Living Out"

"M. X." was recently living in at a hospital but now lives out and receives £150 in lieu. Is tax payable on this £150?

* Yes. Employees living in are in favourable circumstances as regards income tax, and no special concession is made when those circumstances cease to operate.

"Pay as you Earn": Wife's Earnings

P. A.'s wife does part-time locum work, but does not earn more than £80 a year. Tax is being deducted from her earnings.

* As a married woman Mrs. A. is entitled to the special allowance of £80 a year, so that she should not be liable to tax at all taking the year as a whole. It may be, however, that her earnings since April 5 last have exceeded the proportion of the annual £80, in which case some tax would be deducted; but that can be rectified during her next period of locum work. We suggest that P. A. ask the inspector of taxes to confirm that Mrs. A.'s code provides for allowance of the £80 to which she is entitled, and, assuming that to be the case, should then await rectification of the matter on the next occasion that Mrs. A. acts as locumtenent at the institution in question.

"Pay as you Earn": Locumtenent

W. B. inquires whether the fact that he still does some work in connexion with a former practice (which he did not sell) affects the basis of calculating his liability as an "indefinite locum."

* In law clearly "no." As a matter of convenience relatively small Schedule E earnings—e.g., those received as a visiting hospital physician—are frequently omitted from the Schedule E assessments and regarded as outside "pay as you earn" where they can be looked upon as being by-products of a general practice. But the facts in this case are otherwise. W. B.'s employment is the main source of his earnings at present, and "pay as you earn" properly applies.

LETTERS, NOTES, ETC.

Oedema of Ankles in Hot Climate

Dr. JOHN G. MUNRO writes: Dr. Watson Newton's letter on the above subject (Jan. 1, p. 32) prompts me to quote an experience I had of similar cases on a troopship some months ago. The first cases occurred on the second day in the Red Sea. There was a sharp rise in incidence for the next four days, then a gradual decrease, and for the last few days of the voyage only two cases were recorded. Just over 1% of the troops were affected. There were no instances of the complaints among the ship's company or permanent staff. The history in each case was fairly constant—a gradual onset of swelling of both ankles, begun usually on the medial side just below the malleoli and accompanied by tiredness of the feet and by aching or stiffness in and around the ankles. There was no history of trauma that the patient was aware of. Clinically all degrees of oedema were noted, from slight puffiness to an extensive swelling which obliterated the normal contour of the ankle, extending on to the dorsum of the foot and 1 to 3 in. in the leg. In these latter cases there was obvious pitting and sluggishness on pressure. The local temperature was raised at several cases showed mottled dark-blue discoloration similar to that seen in a bad sprain. Function was not unduly interfered with by both active and passive movements were partially restricted by stiffness. There was no oedema of other parts or joints, and so far could be ascertained no renal or cardiac cause for the complaint. The general health remained normal. The treatment prescribed was rest. In severe cases the ankles were supported in elastoplast, and when bed space was available the patient was admitted to the sick bay. The average time for disappearance of signs and symptoms and return to normal duties was four days. The less marked cases were excused duties and advised to rest as much as possible. The recovery took nearly twice as long to recover, perhaps because they did not or could not rest efficiently. The aetiology of this curious complaint seems obscure. At first it was thought that prolonged standing, repeated minor trauma to unsupported ankles (all men wore gym. shoes) from the inevitable climbing of gangways, etc., contributed mainly, especially in men not yet physically hardened. More recently, however, I have seen the same type of case in thoroughly trained infantrymen, on short voyages, who were wearing boots at the time. The incidence here was negligible, however. I would like to hear the opinions of others who may have seen similar cases.

Gonorrhoea in North Africa

B. S. writes: To complete Dr. Campbell's summary (July 3, p. 4) it should be stated that tests had shown adequate absorption of the drug into the blood stream. The paper at once recalls the inadequate absorption of quinine tablets in malaria. What part of the alimentary canal absorbs the drug? Had conditions arisen that hurried the drug along this part or along the whole canal? Has partial inadequate treatment of the civilian population created a resistant coccus?

Marriage and Parenthood

Dr. H. M. DENHOLM-YOUNG (Farnham, Kent) writes: We have agreed that our patients expect us to be able to repair marriages and to prepare them for marriage, and we agree that we were not trained for this as students, but no one has suggested books. May I venture to suggest: for patients of all grades of intelligence, *The Sex Factor in Marriage*, by Dr. Helena Wright (Williams and Norgate Ltd.); for serious study, *Ideal Marriage*, by T. Van de Velde (Hoebermann), and, regarding birth control, *Parenthood: Design or Accident*, by Michael Fielding (Williams and Norgate); and possibly for adolescents, *Men, Women, and God*, by Herbert Gray (Student Christian Movement). The first book, given to the husband, usually repairs a breaking marriage without further advice, and is obtained from medical bookshops.

Concurrent Herpes Zoster and Varicella

Dr. C. H. BARNETT (Winchmore Hill, N.21) writes: Dr. J. J. Manning (July 22, p. 115) stresses that his patient with both herpes zoster and chickenpox is 63 years old. Since varicella is predominantly a disease of childhood and herpes zoster can occur at all ages, examples of the twofold condition would certainly be expected among children in the main if the view mentioned by Dr. Manning that coincidence alone is responsible were correct. The figures do not confirm this expectation, however. Out of 32 similar patients mentioned in British journals, 22 were more than 25 years old. Several were over 60, when varicella is most unusual. Coincidence is therefore unlikely to be the complete explanation.

Hospitality for Doctors' Children

Offers of hospitality for the families of doctors practising in designated areas are still being received. Any reader interested should communicate with the Secretary, British Medical Association, B.M.A. House, Tavistock Square, London, W.C.1.

BRITISH MEDICAL JOURNAL

LONDON SATURDAY AUGUST 26 1944

PSYCHOLOGICAL MEDICINE AND THE FAMILY DOCTOR*

BY

R. D. GILLESPIE, M.D., F.R.C.P., D.P.M.

Physician for Psychological Medicine, Guy's Hospital; Acting Air Commodore, R.A.F.V.R.

The opening of the York Clinic for Psychological Medicine at Guy's is an opportune moment for discussing the applications of psychiatry to general practice. The need for doctors to pay attention to the psychological aspects of medicine has been recognized more and more in the past two decades; but tradition dies hard, even if it is not a very old tradition, and there is still reluctance on the part of many to take any lively interest in psychiatry. The curriculum is partly to blame. Although there was a curriculum conference not many years ago it did not succeed in producing more than recommendations that the teaching of psychological medicine should be supplemented in certain ways. The compulsory part was still left at attendance at lecture-demonstrations in a mental hospital. The fact that mental hospital patients are only part, and numerically a minor part, of the domain of psychiatry was not recognized by making anything else compulsory, nor was it made obligatory to have at least one question in this field included in the final examination. When a subcommittee of the British Medical Association surveyed the field of education in psychological medicine nearly 20 years ago it was discovered that one university in the Empire went so far as to include psychiatry as one of the subjects equivalent with medicine and surgery in the final examination. Now Edinburgh has followed suit at the request of the students themselves. This observation should be printed in italics. But, as Mr. Slesinger often points out to me, with some envy perhaps, the Scottish student is a far-seeing person.

Prevalence of Psychological Disorder

It would be very much to the advantage of medical men generally that more teaching of this sort should be available, not only in the interests of their patients but often in their own. To show how much the psychological aspects of disease matter, it is only necessary to quote the results of investigations that have been made in recent years. At Guy's Hospital, for example, it was found that one-sixth of all those who turned up at general medical out-patient departments were not suffering from any organic disease but from symptoms due to psychological causes. This series of Dr. Bruce Pearson's included over 1,200 cases, and has been supplemented at the same hospital by a study of a further 500 cases by Squad. Ldr. A. M. G. Campbell, who found that 13% were suffering from psychological disorder. Where illness of the more chronic type is concerned the proportion has been found in 1,000 cases to be approximately 35%. This was the figure arrived at by Halliday, acting as medical referee in a district of Scotland. These data are obtained from clinical material of the type that would as a rule appear in general practice.

Where a consulting practice is concerned the position is not very different. Prof. J. A. Ryle told me some years ago that anxiety neurosis was one of the most frequent diagnoses he had to make, and Air Cdre. Conybeare is of a similar opinion—at any rate, so far as war medicine is concerned.

Presenting Symptoms

These figures do not mean, of course, that the patients always or even usually come with their symptoms formulated in psychological terms as depression, worry, or what not, although it is my impression that on the whole they do so now more frequently than they did in the past. Whereas formerly they were apt to complain almost exclusively in terms of physical discomfort, it seems more common nowadays for them to say that they feel nervous or that they cannot concentrate or that their memory is bad. This is probably correlated with the decrease of gross hysterical symptoms in the form of paralysis, blindness, etc., as opposed to frank anxiety states, which have been relatively more frequent in this war in contrast to the last—a difference which some have sought to explain in terms of an alteration in war conditions, but which merely parallels a change that has occurred in civil practice in the intervening 20 years. The late T. A. Ross remarked the same thing in one of his reports of the work of the Cassel Hospital—that in the course of the years it had seemed to him that there had been less tendency for neurotic patients to emphasize bodily complaints and more inclination to talk in terms of fear and worry. I have received very much the same impression in both civil and military practice, and I have sometimes longed for the good old days when paralysed limbs and anaesthetized senses could be demonstrated in Sir Arthur Hurst's graphic manner to both patient and student, and when there was often something much more tangible to get hold of than a phobia or a blank depression of spirits. The change depends partly on public education and partly perhaps on doctors themselves knowing more about these matters as a result of advances in pathology on the one hand and in psychopathology on the other. The discovery of the Babinski reflex made it much more easy to distinguish organic from functional paralysis, just as other discoveries made it impossible for doctors to speak of Parkinsonism any longer as a "functional" disease, as Gowers did in his famous textbook.

"A Rose by Any Other Name"

It still happens, however, that a physical diagnosis covers a fundamentally psychogenic condition. Such diagnoses as "debility," "anaemia," "rheumatism," and "gastritis" are apt to be labels for what is really a psychoneurosis. Years ago Dr. Millais Culpin showed this very well when he produced a statistical table of the incidence of these alleged conditions in a large industrial concern. Taking the sick returns year by year, he found that when the number of diagnoses of anaemia, gastritis, and dysmenorrhoea went up those of neurasthenia, "nerves," and general debility went down; in other words, these are often interchangeable labels. Recently war experience has provided a further illustration of the same thing.

When a special unit was opened for the treatment of rheumatism it was found that more than one-third of the cases sent there were not rheumatic at all but were psychoneurotic in some sense. For example, a man aged 20, whose case was described to me by Wing

* A lecture delivered at Guy's Hospital in May, 1944.

Cmdr. J. Flind and Squad. Ldr. Barber, had complained of the fairly sudden onset of pain in his shoulder-, hip-, and knee-joint on the left side, about nine weeks before admission, associated with attacks of dyspnoea, palpitation, and dizziness. He had breathlessness and palpitation, but no pains, before entering the Service. When he joined up he was given disciplinary training; he felt very low in spirits, complained of aches and pains, and was put to bed. Being allowed up, he was transferred to another station, where his symptoms soon reappeared and he was sent to bed again. It was found that he had always been an excitable worrying person more or less afraid of the dark and upset by the sight of blood; his mother was herself nervous. His symptoms appeared in the Service when he was put to a type of training which he disliked enormously, and reappeared when he was put on guard duty, which he disliked still more. He said frankly that he was "scared stiff of these guards." He had no physical signs, and the only positive findings were psychological ones.

The same thing holds in many cases of appendicitis in which a normal appendix is found on operation. I still remember vividly the first case of this sort that I had under my eye as house-physician. I was not trained in psychological medicine then; but this man's appendix was quite normal, and I noticed during his convalescence that he was inordinately fond of self-display, wearing a gaudy dressing-gown, which he might be said to flaunt in front of the nurses as he strolled about the ward. I have no doubt now that had I known something of psychological medicine then one unnecessary operation could have been avoided. We all know of teeth taken out unnecessarily, on the assumption that symptoms, really psychogenic, were due to dental sepsis, of refractive errors of plus one or minus one dioptré corrected by glasses but without ultimate relief of the headache, which was due to anxiety of some sort; and of exploratory laparotomy with negative findings in, say, a depressive illness.

Psychosomatic Medicine

But it is not only conditions mistakenly diagnosed as physical that are to be accounted for by psychological factors. The term "psychosomatic medicine" covers also conditions which have a definite peripheral pathology of structure but in which psychological factors are important, sometimes the most important, determinants; for example, in some cases of asthma, of certain skin diseases such as prurigo, of duodenal ulcer, and of hyperthyroidism.

Not long ago I saw a man with a fairly widespread pruriginous eruption, which had been very persistent and was associated with a good deal of depression of spirits and insomnia. Repeated and vigorous treatment for his skin did not have any lasting effect. It was then found that his symptoms had begun when he was sent abroad on service and that his going abroad was only the last of a series of efforts to get into a really dangerous enterprise, although he was certainly over the age at which front-line service was usually permitted. He had volunteered for two of the most risky forms of service and had been refused these on account of his age. It was curious that he should have been so unusually persistent in seeking danger. It transpired that he had a sense of shame for having developed neurotic symptoms in the last war so that he was invalided home. Furthermore, he had a great admiration for, and at the same time considerable fear of, his father, who was a very severe man with an impulsive temper. A sense of unworthiness acquired vis-à-vis his father had made him want to live to please him. This apparently was the main driving force of his life, and although he was married and had a family his great desire was to justify himself in what he thought was his father's opinion, and it was this that caused him to volunteer for the dangerous jobs. In actual fact the attempt to face the rigours of a campaign had made him tense and nervous, had upset his health and helped to bring on his skin eruption, and kept him miserable at what he considered his failure. Discussion of this attitude and the realization of its immaturity enabled skin treatment to proceed with final success.

Another patient with impetigo which was suspiciously persistent turned out to be suffering from acute apprehension about return to duty—not because he was a coward, but because he had had an extremely disturbing experience which had stamped itself on his mind in a way that made him feel it was impossible to face a recurrence of the same situation, although previously he had behaved with courage and devotion.

It is possible to show that asthma has all sorts of relationships to mental events: that hyperthyroidism is especially apt to occur in people who have been anxious over a long period; and that rheumatoid arthritis is found more often in people whose emotional furniture is disarranged. Naturally the

relationship of the pathological bodily state to the psychological aspects is a very varied one, but the simplest is where the precipitating factor is psychological—for example, in asthma sustained by an unhappy domestic situation, or, as Rogersen showed, in children in whom the development of asthma may be precipitated by an over-anxious parental attitude.

Medical Scepticism

It is of course natural for anyone approaching the problem from the angle of general medicine to be very sceptical about the relationship of psychological disturbance to what is obviously physical disease. I remember a meeting of the Asthma Club many years ago, when it was obvious that some of the members were extremely resistant to the suggestion that an asthmatic attack could be precipitated by an idea just as much as by an injection of something. But appreciation even of the "conditioned reflex" process would have prevented anyone being surprised by this.

The story of the woman who had an asthmatic attack on seeing a bouquet of artificial roses has been paralleled a number of times; for example, in the case, recorded in an American journal, of a woman who was allergic to onions and who immediately developed conjunctivitis and a stopped-up nose on seeing, apparently, onion peelings on the rug. On withdrawing to another room, she told the maid that there were onion peelings on the floor and they had made her sick. The maid apologized and said they would be removed immediately, but soon returned and said that they were the remains of a narcissus bulb which a dog had chewed.

This type of thing is one of the simplest examples of the effect of a psychological fact on what looks like an entirely bodily ailment; but it is worth knowing that a great many more complicated psychological patterns—for example, a domestic situation—can have the same effect. It has also been noticed that a psychological upset, or at least a period of psychological tension, often precedes the appearance of a duodenal or even a gastric ulcer.

Terminology

The general practitioner is apt to treat psychiatry as an esoteric mystery, and this is probably in part the fault of the professors of the subject, but not entirely so. Many doctors profess to be deterred by the terminology, but I am inclined to think that this is a kind of rationalization for a refusal to become interested. Actually there is no branch of medicine in which the general practitioner is more fitted to undertake or in which he has more opportunities. First, as to the objection about terminology: the best practical work in the English language about the psychological treatment of patients is T. A. Ross's *Common Neuroses*. It is written in the simplest English, and there is hardly a technical term anywhere. It describes mainly psychoneurotic conditions. But if the terminology is taken as a whole it will be found—for example, in a standard textbook of psychiatry such as Henderson's and mine—that so far as syndromes are concerned not more than half a dozen names are necessary for classification purposes, and of the half-dozen major groups the most outlandish designation of the lot (namely, schizophrenia) has become almost a household word—thanks, it is true, largely to the sensational press. It is only when you come to psycho-analytic terminology that much special knowledge is required; but the psycho-analytical method is highly specialized, and as it is of practical use, for a variety of reasons, only in a minority of psychological illnesses this problem need not trouble the general practitioner.

Special Opportunities of the Family Doctor

On the positive side the family doctor has certain advantages. First and foremost he has, or should have, a good working knowledge of human nature. General practice is one of the best training grounds in that subject. Psychological illness is, roughly speaking, a matter of human beings in personal distress very often because of their ignorance, shortcomings, disappointments, and dissatisfactions, and still more often because of their fears. The study of human nature is therefore profitable not only in teaching one how to handle one's patients but in knowing how to cure, or at least to help, anything from one-sixth to one-third (some would say more) of the illnesses for which they consult their doctor. In this sense anyone who cares to

study this topic is capable of becoming a psychotherapist up to a point although few people will deny that the best psychotherapists are born as well as made. It is however, to be expected that so long as doctors as a whole tend rather to shun the psychological aspects of their practice, the number of irregular practitioners in this field is likely to be considerable. Many of the triumphs of those who practise suggestion in various disguises are achieved in patients in whom the doctors have not recognized the psychological basis for their illness. The medical man, however, has certain advantages of his own, although his very knowledge prevents him having that sublime confidence which comes so naturally to the quack. In the first place, the psychological distress which the patient is suffering expresses itself very often in terms of bodily discomfort—indigestion, palpitation, and so on—and only a doctor is in an authoritative position to evaluate such symptoms. Unfortunately medical education tends to over-emphasize the structural aspects of pathology. It is a pity that the student's physiological work does not concern itself a good deal more with the effects of the emotions on the bodily functions. He might then never forget that when symptoms of a disturbed organ are presented to him one of the causes that he must always remember is the emotional or psychological one. This, however, is the last that he usually thinks of, and a great deal of time may be spent on laboratory investigation before the patient is even asked whether he is worried or not. Psychological factors are so pervasive that they should enter into consideration in almost any differential diagnosis in the first instance. This at any rate, would be safer than not considering them at all.

Suggestion

There is another advantage that the doctor possesses. Like the priest he is a symbol of mysterious power in the eyes of his patients and has in consequence a great capacity for allaying anxiety. We are apt to forget how thin is the veneer of culture and adult control, and how often in times of distress, especially if the distress is fundamentally distress of mind rather than of the body, people tend to think in primitive terms. It is in such circumstances that suggestion is particularly potent, yet few doctors consciously practise suggestion, although they are in a position to use a very enlightened type of it since they combine the authority conferred on them by the more childish aspects of their patients' minds with the enlightenment contributed by their own education in disease.

I am not advocating that suggestion as such should be widely used, yet it is more appropriate for the ill educated, and is sometimes the only form of psychological treatment that is applicable to them. How powerful it is is illustrated by the famous story told by Dr John Brown of Edinburgh, who reported the case of a labouring man affected with colic, for whom he prescribed some medicine, directing him to take it and return in a fortnight assuring him that he would be quite well. At the appointed time the man returned entirely relieved and jubilant. The doctor was gratified at the manifest improvement in his patient's condition and asked to see the prescription which he had given him, whereupon the man explained that he had taken it as he had understood the directions, by swallowing the paper!

Education and Suggestibility

I used to think that the more educated people were the less suggestible they became, but this is certainly not by any means always the case. Many years ago I acted as assessor for the Asthma Research Council to a doctor who claimed to cure asthma by suggestion. I selected 12 asthmatic patients for him and he proceeded to use his method in my presence. He employed what to my mind was a very simple form of suggestion and after one session three of the 12 patients proclaimed themselves better, and these were certainly among the most intelligent of the small group. Similarly Prof Witts and his co-workers found at the Asthma Clinic at Guy's that they had almost as much success for a time with injections of distilled water as they had with vaccines and the like.

The point is that suggestion is the simplest form of psychotherapy and does not require a technical knowledge of psychopathology in the modern sense. The family doctor is in a peculiarly good position to apply it, because of his special

prestige with the patient. It is true that he uses suggestion all the time, more or less unconsciously, when he gives a bottle of medicine or some other treatment that he himself has faith in, but deliberate and discriminating use of suggestion as an additional weapon is at present rather neglected.

Iatrogeny

There is a negative aspect of this matter of suggestion which is not so much to our credit. There is a chapter omitted from medical textbooks which might be headed Iatrogenic Diseases—that is to say, diseases produced by doctors. It is not well enough realized that it is dangerous to give a label to a set of symptoms of disease until you are convinced that it is the right one. If a syndrome is psychologically produced (which of course the patient does not know), and if the doctor also does not know this and calls it gastritis because the patient complains of indigestion, or a weak heart because he complains of breathlessness or precordial pain, or even if he attaches to it some cabalistic letters such as D A H, then he has implanted a suggestion in the patient's mind which fixes his anxiety in a way which, if not quite indelible, is at any rate very hard to undo.

The advance of clinical knowledge has definitely limited the scope for iatrogeny. The number of young people who were made into chronic semi-invalids by the diagnosis of a "weak heart" on the strength of a complaint of breathlessness or palpitation or in the pre Mackenzie era, on the basis of a murmur must be very much less than it was, and though no doubt we have all encountered a case or two of the sort, colitis is not diagnosed on such dubious grounds now as in Axel Munthe's day. "Dropped kidney" is not heard of any longer as a cause of general ill health, but the old notions of "dropped stomach" and "dropped colon" die hard in spite of Hurst's demonstration years ago that a significant proportion of Guy's winning fifteens carried their stomach nearly in the pelvis. One still finds an occasional belt festooning the abdomens of neurotic patients. A prop of that sort only fixed the patient's conviction that he is physically incapable. All diets and regimes, and often medicines, that are not founded on definite physical findings—not necessarily x ray or laboratory findings, but those based on a satisfactory clinical history and examination—are apt to produce the same result. This is even truer of operations that have been performed unnecessarily. The experience of such an operation is very impressive, and it is difficult for the doctor who comes afterwards to convince the patient that his symptoms are psychogenic and rather unhappy for the doctor who has the task of somehow getting over the fact that a colleague of at least equal standing has gone the length of operating. I have known such operations to be performed for broken hearts, angry fathers, sexual guilt, depression of spirits, anxiety of all sorts, and even on account of mistaken pride—the patient herself knowing that she had no physical ailment really, but lacking the courage to tell her parents that she had simply been giving a demonstration and was not ill at all. In that instance the play went on and the appendix came out and the patient was no better a character afterwards, but rather the reverse. It is however, only fair to observe that the number of operations performed in the mistaken belief that an organic cause exists, when the condition is really psychogenic is less than is sometimes supposed as L. H. Ziegler has shown.

Types of Psychogenesis

It is worth while pointing out, what has not usually been said, that in the psychological approach to patients the family doctor has advantages not possessed by any specialist or consultant. The reason for this becomes clearer when we remember that the main causes of psychological ill health can be classified as (a) constitutional, (b) situational (to use an ugly but self-explanatory word), and (c) historical in the sense of something dependent on events far back in the patient's life. It is especially in a and b that the family doctor possesses advantages. In connexion with both it is necessary to remember that there is no apparatus or technique which will make even the most able specialist always certain when the patient is telling the truth or is concealing it and so he has to depend for some of his information on outside sources, which are often not nearly so accessible to him as they are to the family doctor.

Again, many psychological problems are closely related to the character and temperament of the patient, and there is no satisfactory laboratory or consulting-room test of character and temperament, although some things are helpful. Nothing that we have at present surpasses or even as a rule equals in reliability the knowledge of the day-to-day behaviour of an individual such as is accessible to those who are in contact with him in his, so to speak, natural surroundings. In contrast with the consulting-room—which represents a special and artificial environment in which it is very easy (in fact, almost inevitable for the patient, at any rate in his first interview) to display a façade that is extremely artificial—the family doctor is much more likely to be in a position to know when the patient is being truthful and to learn something about his temperament, not only from contact with the man himself but also from his relatives and possibly some of his friends.

These considerations have a very important bearing on the evaluation of the various types of causal factor, whether constitutional, situational, or historical. The assessment of the constitutional factor, for example, depends very much on a knowledge of the family history. A family whose child I was treating concealed from me for a whole year the fact that an uncle had died insane and that the brother was a "near-miss" to schizophrenia. The family doctor had sent this case to me by post, as it were, and I had not had an opportunity of talking with him. It is astounding with what aplomb people will say there is no mental illness in their family. One realizes this especially when, from some other quarter not known to either patient or relatives, one happens to hear that there is. Contrast this position with the possibilities of the family doctor, especially if he has lived in the same district a considerable time and knows the people. Sir Thomas Clouston made an inquiry into the family history of 83 families taken at random in a country parish in Scotland, all the members of which were personally known to him for three generations.

He said, "I took every family I really knew, and no others. I made no selection. They were all country people—decent folks, hard-working, thrifty, few very poor, indeed mostly money-loving, with scarcely any drunkards. . . . I took advantage of my intimate knowledge of the people as a doctor to count the lesser attacks of melancholia, the milder delusional states, and the milder degrees of imbecility that would not have gone into any public statistics of lunacy or census schedules. Still, they were all mental diseases or defects just as truly, from the scientific point of view, as our acutest case in Morningside" (the Royal Edinburgh Mental Hospital). "The result was this—that, of those 83 families, I knew that in 41 of them one or other of these four diseases had occurred."

His remarks refer, of course, only to more or less strictly mental diseases; but the same is just as true, and even more important because they are in greater number, of the conditions that we now know as psychoneurotic and psychopathic. There has been a tendency on the part of over-enthusiastic psychotherapists to neglect, and not to trouble to evaluate, the constitutional factor in the patients whom they undertake to treat. There is a fair amount of evidence that such disorders as phobias, which are often supposed to be entirely determined by complexes, are far more often apt to arise in those whose ancestry shows some neurotic stigmata as well.

I am thinking, for example, of a patient of mine who has a phobia of open spaces which prevents him from going far from his home, and whose father had a similar phobia; and of another patient with a such-like difficulty whose father was eccentric and extremely reluctant to meet anyone outside his immediate family. Another patient occurs to me who had a great deal of neurotic anxiety, whose mother had epilepsy, and whose uncle was insane. Instances of that sort are frequent enough to make the conclusion extremely probable that there is more often a constitutional factor in the psychoneurotic form of illness than has been admitted in the sometimes rather indiscriminating enthusiasm for psychotherapy. Dr. Felix Brown's researches on the familial incidence of psychoneurosis support this view.

A knowledge of these things, which certainly comes more readily to the family doctor, is of value in prognosis. It is of course desirable that the family doctor should reside for a considerable time in the same district. The rolling stone in medical practice will certainly gather very little of this essential knowledge. One of the best letters I have ever had about a patient came from an old practitioner in the North of England who said that he had known the young woman whom I was

to see since she was a baby, and had known her mother since she was a baby, and had also known the patient's grandmother. Such a long perspective is of course very rare, and I often think that the death of an old doctor is in this respect a much greater loss to the community he serves than we are apt to think. It is particularly in the psychological aspect of medicine that the life history is important. The specialist envies the family doctor his opportunities in this regard. The value of a life history obtained from direct observation from childhood into adult life is so great that it has always been my ambition to collect case records of the difficult or nervous children referred to us at Guy's, so that we could get in touch with them in their adult life. Healy has recently done this in America, but no psychiatrist has a similar opportunity here; and even with the best arrangements in the world it would be very difficult for the specialist to keep track for any length of time. For the general practitioner in not too urban a district the chances are very much better and his data potentially much more reliable. Healy and his associates took the opportunity of correlating their patients' childhood as they knew it with the history given retrospectively afterwards, and found striking differences, partly as a result, no doubt, of the falsification by the rosy mists of memory, or, more technically speaking, by the workings of selective repression.

"Situational" Factors

With regard to situational factors, as distinct from constitutional and historical ones, the family doctor has a special part to play and special opportunities for playing it. In fact, his opportunities of collecting data from the patients' immediate circumstances and from the patients' life history put him in a unique position as a kind of social pathologist. It seems to me that this may even be one of his chief roles in the future, which no one can take from him. One often hears that he is losing portions of his work to this clinic and to that organization, and so forth, but the fact that he lives among the people whom he serves, and especially knows something of their family life, means that he can fulfil a function that no one else will be in a position to do. I cannot see the English public admitting social workers to their homes on the same terms as the family doctor—not, at any rate, if the latter lives up to his best tradition and reputation.

Moynihan used to contrast the pathology of the dead-house, or morbid anatomy, with the pathology of the living. Psychological medicine is really the pathology of life or social pathology. This pathology concerns itself with the jealousies, disappointments, annoyances, grievances, dissatisfactions, fears, anxieties, and so on that produce the aches and pains that we call functional. The lumbar pain without discoverable basis which the gardener had yesterday, and which disabled him for the time being, can be traced to some annoyance at his master's attitude. The headaches that the dutiful daughter complains of may arise, if she did but know it, from a smouldering resentment at her invalid mother, whose invalidism in turn may be just a method of keeping her daughter at home; while Mrs. Jones's asthma may be nothing but an expression of her aversion to her husband.

The specialist confronted with functional symptoms due to situations of this kind has to start from scratch, and is very much at the mercy of what the patients care to tell him. I have known patients conceal for months facts about themselves which were fundamental and not at all unconscious, and this not only from myself, who am perhaps simple-minded, but from my colleagues. The family doctor, on the other hand, may know these things already. The fundamental truth implied in the term "situational" is that emotional situations generated by unsatisfactory circumstances and disappointing relations with other people cause emotional tension that generates symptoms—mental or *prima facie* physical—which are the complaints the patient brings to the doctor. The simplest situation is where the job is unsuitable.

For example, a young woman, a telephone operator, complained of attacks of faintness and dizziness which occurred at her work. Physically she was perfectly sound; intellectually she was considerably above the average and had won a scholarship at school; but on leaving she had to take a post which would quickly bring remuneration, as her father was dead and her mother was largely dependent on what the daughter could earn. Her desire to become a school

mistress was thus frustrated, and she became a telephone operator. The technique, such as it is, was easily mastered. This done, the work merely became monotonous, giving her ample time to ruminate over her frustrated career and later (in the sequence that is common) on her health. The usual hypochondriacal consequences ensued.

Again, there was the case of an elderly man, the father of a large family, who had suffered from headaches for thirty years—headaches which left him during his holidays. He was an intelligent man, who had worked on the same routine job, long since learnt by heart, for 40 years. For most of that time he had been heartily sick of the work, but he had hoped for promotion. At length it became obvious that he could justifiably hope no longer, and then the headaches which had already begun became permanently installed. Here, too, was a neurosis resulting from occupational misfit and monotony, but again there were other factors—in this case the disappointment of legitimate ambition.

The same situation may of course be pathogenic for one patient and not for another, and this is where knowledge of the character and temperament of the individual will be of the greatest service. This group of disorders is also one which the family doctor is fairly often in a good position to assess and even to treat first, by explaining to the patient how symptoms are related to emotional tension, then from his knowledge of the circumstances, advising whether the situation can be altered, as by change of job, or whether it must be faced, and if necessary, not forgetting to point out where a fault of outlook or a defect of character has been mainly responsible for the failure of the patient to solve the difficulty on his own.

The usual objection made by the family doctor to the psychological side of medicine is his lack of time. The late T. A. Ross, who was himself in general practice for 20 years, used to reply that the proper use of time was necessary, and that an interest in psychological medicine would save the doctor's time in the long run. Another objection that may be urged is this: How can the general practitioner be expected to know the circumstances, dispositions, and temperaments of, say, 2,000 possible patients? But psychological disorders are very often related to family affairs, and although the general practitioner may have a clientele of 1,000 or 2,000 it is probable that the total number of family groups involved is considerably less than this and the more neurotic families will probably consult him a good deal oftener than the rest.

"Complex" Factors

The third large group of psychological disorders consists of those in which neither circumstances nor situational factors are important, and the symptoms of which are a legacy of some far distant miscarriage of psychological development. This, on the therapeutic side, is the specialist's domain, since the discovery of the pathological processes and their rectification require a special technique of exploration and many hours of painstaking work. But even here the family doctor can give useful hints from his knowledge of the patient's life history. Many of the complex-determined psychoneuroses originate in childhood or even in infancy. One of the most potent causes is emotional insecurity on account of insufficient parental love, or, as it is usually called, parental rejection. Few people are in a better position than the family doctor to know whether a child has been wanted or not, and this knowledge may be a key to all that goes on subsequently. In fact, in the field of child psychiatry itself the family doctor has opportunities which the specialist might well envy, since he is often present in the early days of life and sees the mother's attitude, and whether there is over-protection or rejection, or both, these attitudes being so often determining factors in the subsequent behaviour of the difficult or the neurotic child.

Views on the deeper pathology of neuroses have been drifting away from exclusive preoccupation with the Oedipus complex—a development which might well be beyond anyone's observation at the time—to a more comprehensive theory of the causation of neuroses. It will be seen that, although the type of psychoneurosis that is dependent on early faults of psychological development may probably always remain the particular field of the specialist, nevertheless the family doctor can collaborate with him in providing bits of information that may give valuable hints on the nature of the early causes.

Sexual Factors

There is one type of situational problem which I have left for separate mention until now, and that is the sexual. In calling it situational I am of course not forgetting that its roots may extend far into the individual's past. It has long struck me as peculiar that practically no medical school in the country offers a course in sexual psychopathology to its students. I suppose it means that the parental attitude of the medical schools parallels the attitude of most parents in this country, in that it prefers to leave the young to find out for themselves. This is not a satisfactory position for a doctor, who as soon as he has qualified is regarded by the lay public as a repository of mysterious knowledge in this respect. It seems only fair to the doctor, and also to the public, that he should be provided with a modicum of information on the nature and cure of the most common group of maladies about which he is likely to be consulted.

The most frequent inquiries concern impotence, frigidity, masturbation, and homosexuality. It has been well said of impotence by Dr Ernest Jones that it is either very easy or very difficult to cure and there is every reason to suppose that many such cases can be, and probably many of them are, cured by a doctor who understands that their commonest causes are ignorance, fear, and misinterpretation of some previous experience. The deeper causes, often to be sought out only by the professed psychopathologist, are chiefly guilt-feelings and over-attachment to the mother. Similar factors, *mutatis mutandis* are at the basis of frigidity. Homosexuality occasionally yields to superficial exploration and persuasion, but is more often a job for the specialist, who succeeds in curing only a minority of such cases. Difficulties of this sort naturally have ramifications in problems of domestic harmony. This may be the guise in which the thing first presents itself to the doctor: the other way is in the form of psychoneurotic symptoms elsewhere in the body, aches and pains generally, all of which are sometimes the direct result of sexual inadequacy or sexual dissatisfaction. But I imagine that a large proportion of doctors are shy of knowing these things about their patients and the patients are shy of telling their doctors, because it takes time to get down to a topic of that sort, and you cannot possibly broach it to someone who has only a short time to give you. It is nevertheless not true that the majority of nervous conditions, even in women, are the result of obvious sexual situations of this sort, but they do undoubtedly play a part in some of them.

Prognosis

The hysterical conditions commonly so called—that is to say, the paralyses and sensory disturbances—can usually be cured fairly rapidly by persuasion, at any rate so far as the symptoms themselves are concerned, but, having done this you may find in a number of cases that you are left with a state of psychoneurotic anxiety which replaces the headaches and what not previously complained of.

It is my impression that one will only completely cure a hysteric if he has ceased to have a motive for his disability and merely wants to know how to recover without losing his self respect. This accounts for some of the more dramatic cures of hysterical paralysis in the last war: few of these patients were expected to return to the front. Some, in peace-time conditions, you can cure even when the motive still exists, by showing them what that motive is. Other cases, more rare, depend on unconscious mental processes associated often with guilt-feelings such as only professional psychopathologists can hope to find and tackle.

As regards psychoneurotic anxiety states, some of which are called by the Freudians "anxiety hysteria," prognosis for the "situational" group is good as a rule, so also is the prognosis for those cases of this type which arise from faulty upbringing and the acquisition of wrong ideals, and so forth, but the cases that depend on historical factors in the unconscious await the advent of the skilled psychotherapist before much is likely to happen in them. In the two groups together the statistics in the Cassel Hospital collected by T. A. Ross showed a recovery or "much improved" rate of 76%. The data from the various psycho-analytic clinics recently collected by Knight showed a combined recovery rate of "cured" and "much improved" of 61% in approximately the same groups.

The trouble in assessing these results is the lack of satisfactory control groups, and there is no doubt that in some conditions a certain proportion of these people tend to get well themselves in the course of time. Any satisfactory investigation would require to distinguish not only loss of symptoms but durability of cure and its other features, such as the change in the social qualities of the patient concerned and the improvement in his general adaptation to life. Among cases of the obsessional or obsessive-compulsive variety the data are conflicting; I have no doubt that there are some cases which without special treatment would not improve at all or would improve very little, but it has to be remembered that here also there is a spontaneous recovery rate. I find statistics of this sort very unsatisfactory and the individual case much more convincing. Statistics should also take into account the duration of a treated case compared with one untreated. I believe that with treatment many psychoneurotic illnesses are shortened; and this, in fact, it would be fair to say—that psychoneurotic conditions are among the most curable of the chronic illnesses the doctor is called upon to treat.

Conclusion

There is an outstanding fact which should commend the practice of psychological medicine to the clinician—and the family doctor is first and foremost a clinician. It is this: that psychological medicine remains pre-eminently a field in which the clinical method, independent of the laboratory and the test-tube, is still the fundamental one. Even the most recondite psychiatric history—such as, for example, that which psychoanalysis involves—is essentially a clinical history of the patient. This history of the patient, which should be a history not only of his symptoms but of his life as an individual, is both a means of diagnosis and the foundation of treatment. For diagnosis, of course, one has to know as well the natural history of physical diseases, while to use the detailed history for the purpose of treatment requires a knowledge of the principles of psychological medicine. But these principles in what I have called the "situational," and even in many of the historically determined conditions, are simple and can be applied successfully by anyone who cares to give his attention consistently to this aspect of his practice.

AN EPISODE OF "HOMOLOGOUS SERUM JAUNDICE"*

BY

W. H. BRADLEY, D.M.

J. F. LOUTIT, B.M.

AND

KATE MAUNSELL, M.D.

The occurrence of jaundice in man after the administration of human blood products (plasma and serum) is now a well-recognized phenomenon, and a review of this "homologous serum jaundice" was recently published. The jaundice, which is of hepatic origin, is readily distinguished from the haemolytic icterus which may arise immediately after transfusion with incompatible blood or out-of-date stored blood. Clinically it is similar to, if not indistinguishable from, epidemic hepatitis (catarrhal jaundice), but the incubation period is unusually long—commonly from 2 to 3 months, in contradistinction to the 20- to 40-day period believed to occur in epidemic hepatitis.

A high incidence (57%) of this jaundice has been observed among 71 subjects during the course of an investigation into allergic reactions to human serum. All these subjects received pooled human serum from a single batch (No. 034); a few of them received in addition whole blood or serum from other batches. Batch 034 was, however, the only common factor, and was clearly incriminated as being icterogenic. Subsequently, icterogenicity was confirmed by the results of the deliberate

administration of batch 034 to four volunteer cases of rheumatoid arthritis in which it was desired to produce jaundice for therapeutic reasons.

From this experience it is possible to draw certain conclusions concerning the routes of administration and the effective dosage of icterogenic material: some of the findings are therefore reported.

Materials Used

No. 034 was a routine batch of dried serum issued by the Medical Research Council Drying Unit. It had been prepared from 106 litres of pooled, filtered human serum collected in late April, 1943, from donors in the London area. Sterility tests before and after filtration were negative, and the batch was issued in units (bottles) each equivalent to 400 c.cm. of liquid serum. The units were numbered 1 to 250: Nos. 8- to 146 were received by this depot as its quota of the batch and were reserved for purposes of investigation.

The other batches of serum also administered to some of the subjects were:

(a) *Batch 045.*—This was another routine batch of dried human serum issued by the Medical Research Council Drying Unit, and was prepared from 177 litres of serum from donors in the London area and East Sussex. It was collected in early June, 1943, and sterility tests before and after filtration were negative. Nos. 1 to 102 were received at this depot.

(b) *Pool 0.*—This was a small pool of serum prepared locally, and after Seitz filtration, kept frozen until used.

Any bottle of batches 034 and 045 was assumed to be of identical composition with any other bottle in the same batch.

Methods of Administration

Intradermal Tests.—Several bottles of batch 034 dried serum were reconstituted to normal strength with 400 c.cm. of sterile distilled water taken at random from stocks prepared at this depot. The resultant liquid was partitioned in 2-c.cm. aliquots into sterile test-tubes and kept frozen at 5° F. till required. It was used on numerous days, on each of which one or more tubes were thawed out and a sterile tuberculin syringe was charged with the fluid. Any unused fluid remaining in an opened tube was discarded at the end of the day. The same syringe and needle might be employed for several tests on the same day without sterilization between tests, but after each day's use the syringe was cleaned in chromic acid and resterilized. Needles were thoroughly rinsed with water and resterilized daily. Sterilization was by dry heat (160° C. for 2 hours).

For the intradermal test two intracutaneous injections of the reconstituted serum, each of 0.05 c.cm., were made into the skin of the back in parallel with extracts of dust, pollen, animal hair, etc., and carbol saline.

Transfusions.—A bottle of dried serum was reconstituted to 400 c.cm. as above or, in the case of pool 0, the serum was thawed out. Each transfusion was administered in approximately 30 minutes. This applied to all except the four transfusions, given to rheumatoid arthritis patients, who each received 50 c.cm. of reconstituted dried serum (batch 045) added to 450 c.cm. of a group O concentrated red cell suspension.

Cases

Group 1.—47 subjects received intradermal skin tests on one to three occasions with batch 034 only. 25 of the 47 were allergic subjects (hay-fever, bronchial asthma, etc.).

Group 2.—9 subjects received intradermal skin tests and serum transfusions on one to three occasions with batch 034 only. 7 of these were allergic subjects.

Group 3.—19 subjects received skin tests or transfusions, or both, with batch 034, and, in addition, tests or transfusions with other human material (pool 0, batch 045, concentrated red cells). Of these, 7 were allergic subjects, 8 were non-allergic controls, and 4 were the cases of rheumatoid arthritis.

Results

All except two subjects who could not be traced were followed up for at least 150 days after exposure. The results

* A report to the Medical Research Council from the S.W. London Blood Supply Depot

are summarized in the accompanying Table. Of the 47 cases (group 1) who had received batch 034 only as skin tests, 26 developed jaundice. Similarly, of the 9 (group 2) who had batch 034 only as skin tests and transfusions, 5 developed jaundice. The latent period in these cases, calculated from the date of the first or only administration of serum up to the

Table showing Incidence of Jaundice following Intradermal Tests and Transfusions of Reconstituted Dried Serum (Batch 034)

Group	Cases	Clinical Signs		Latent Period	
		Nil	Jaundice	Mean (Days)	Range (Days)
1 Intradermal tests only	47	21	26	71	46-104
2 Intradermal tests and transfusions	9	4	5	60	45-79
3 Intradermal tests and, or transfusions + other human material	19	8	11	59	45-96

date of onset of the jaundice, was from 45 to 104 days. This is the maximum latent period; it assumes that the patient had been affected by the first introduction of serum. The date of onset of jaundice was taken as the end-point of the latent period, since in most cases, in retrospect, it was possible to ascertain this date, whereas the date of onset of prodromal symptoms could not be determined.

Of the 19 cases (group 3) who received other materials as well as batch 034, 11 developed jaundice. The latent period, calculated from the date of the first or only administration of batch 034, ranged from 45 to 96 days. Several subjects in this group received material from batch 045. From subsequent investigations there is reason to believe that this batch is also ieterogenic.

The attack rate was of the same order whether the serum had been given intradermally or intravenously, and whether it had been given as a single dose or in repeated doses. The severity of hepatitis, which in all cases was mild or moderate in degree only, also appeared to be unrelated to the size, the route, or the frequency of injection. There was a suggestion, however, that the latent period was shorter when the material was given in the larger or in repeated doses (see Fig.). There is no evidence, so far, that permanent liver damage ensued.

GROUP	QUANTITY c.c.m.	LATENT PERIOD							
I INTRADERMAL TESTS	0.1-0.3
II TRANSFUSIONS	1200 800
III INTRADERMAL TESTS	0.1-0.3
TRANSFUSIONS	50-1200
	DAYS	40	50	60	70	80	90	100	

Chart showing latent periods before onset of jaundice after intradermal tests and transfusions of reconstituted dried serum (batch 034).

The incidence of jaundice was no greater in the allergic subjects than in the normal controls.

Discussion

Since the publication of the Ministry of Health's Memorandum on Homologous Serum Jaundice (1943) the occurrence of the syndrome in this country has been mentioned in several reports (Morgan and Williamson, 1943; Dible, McMichael, and Sherlock, 1943; Steiner, 1944; MacCallum and Bauer, 1944; Beeson, Chesney, and McFarlan, 1944). Nevertheless, the cases of jaundice in the present series had been regarded as "catarrhal jaundice" and the association with the administration of blood products was at first not recognized. The diagnosis of homologous serum jaundice was established only by this follow-up.

When the syndrome occurs after inoculation (measles convalescent serum, yellow-fever vaccine, etc.) it is relatively easy

to detect ieterogenic batches of material, because in most instances serum from only a single batch has been given. When jaundice follows transfusion it may be impossible to decide which is the causative batch, because in the usual transfusion practice several batches of plasma or serum may be administered to a single patient and not infrequently whole blood is given as well. In the present series groups 1 and 2 resemble jaundice following inoculation in that only one batch (034) was administered; group 3 cases are more comparable with those seen in transfusion practice, and if groups 1 and 2 had not been studied simultaneously it would have been more difficult to attribute the jaundice to the causative batch. All the subjects, except the 4 cases of rheumatoid arthritis, also received injections of allergens, but we have no reason to believe that these produce hepatitis.

The attack rate—57% of exposed subjects—is the highest so far recorded in any series of homologous serum jaundice. It must, however, be remembered that opportunities for following up in this series were unusually good. The jaundice was not severe and there was apparently no correlation between dosage and virulence. In group 1 the dose was minute (0.1 to 0.3 c.c.m.); in group 2 two subjects received 1,200 c.c.m. and three subjects 800 c.c.m.—that is, 12,000 and 8,000 times the lowest group 1 dose. The group 1 dose is comparable to the dose recorded by MacCallum and Bauer in yellow-fever vaccine jaundice. Intradermal injections would therefore seem to be as effective as the intravenous and subcutaneous routes.

One possible contact case occurred. A subject in group 2, first injected on July 1, 1943, developed jaundice on Aug. 16. A cousin who had been living with this patient until Aug. 9 developed jaundice 31 days after the last contact. This may have been a random case of epidemic hepatitis, but an alternative source of infection could not be established.

In this series the clinical features (Livingstone, personal communication) and the biochemical findings (Gray, personal communication) were indistinguishable from those of epidemic hepatitis. Dible, McMichael, and Sherlock have reported their inability to distinguish histologically between biopsy material from cases of epidemic hepatitis and that from cases of homologous serum jaundice. For the diagnosis of the latter condition, therefore, one must rely upon the history of injection or transfusion of human material during the preceding few months.

Ieterogenic batches of human serum and plasma cannot be detected by any laboratory or animal tests. Their recognition is possible only when accurate records of the batch and bottle numbers of blood products given to patients are kept and when a careful follow-up of all recipients is practised for some months afterwards. In the present series the generous co-operation of numerous medical officers of health and practising physicians made a 97% follow-up possible.

Summary

Homologous serum jaundice has followed the administration of a particular batch of pooled human serum.

Jaundice occurred in 57% of the cases exposed.

The dose of homologous serum administered varied from 0.1 to 1,200 c.c.m.

The severity of the disease was not related to the dosage of serum given or to the route of administration.

The Colonial Office has issued through H.M. Stationery Office (Colonial No. 187; price 6d.) a report of the West Indian Conference held in Barbados last March. Among the matters reported on by committees were the means for raising the nutritional level; planning of public works for the improvement of agriculture, education, housing, and public health; and health protection and quarantine. The conference took place under the auspices of the Anglo-American Caribbean Commission, and it is planned to hold another within the next ten months.

LATE RESULTS OF CLOSED INTRAPLEURAL PNEUMOLYSIS

BY

PETER W. EDWARDS, M.B.

A. CLARK PENMAN, M.D.

AND

J. LOGAN, M.B., D.P.H.

(From the Cheshire Joint Sanatorium)

The difficulties of statistical evaluation of artificial pneumothorax treatment are well known. It is now recognized that crude statistics such as those of Drolet (1943) and Soderstrom (1941)—which do not take account of the effectiveness of the collapse—are weighted against pneumothorax by the inclusion of a large proportion of cases in which the A.P. was either useless or positively harmful (Rafferty, 1943).

The late results of pneumothorax treatment depend largely on the efficiency of the collapse obtained (Hjaltestad and Torning, 1939; Jennings *et al.*, 1940), and since it has been shown that it is possible, by the use of internal pneumolysis, to improve the collapse in a large proportion of pneumothoraces (Edwards and Lynn, 1939; Wollaston, 1940), it seems to us that for the efficient practice of pneumothorax treatment this operation should be readily available and should be freely used when indicated.

Edwards and Lynn (1939) reported the immediate result of internal pneumolysis on 235 patients. These have now been followed up for five years. Bilateral operations and thoracoscopies without division of adhesions have been excluded from this series, and the number brought up to 200 consecutive cases of pulmonary tuberculosis treated by artificial pneumothorax with unilateral division of adhesions by closed intrapleural pneumolysis. When the indications existed this treatment was supplemented by phrenic evulsion (110 cases), and all patients underwent a strict course of sanatorium routine.

All patients were classified according to the Ministry of Health classification on admission to the sanatorium. The poor quality of the clinical material is shown by the fact that 41% of the series fell into the T.B. + 3 group, 49% were T.B. + 2, and the remaining 10% were either T.B. + 1 or T.B. minus. In all but seven of the 200 cases there was cavitation in the treated lung, and 97 had multiple cavities.

Radiological Result of Operation

The present series of 200 pneumothoraces with pneumolysis have been grouped according to the degree of collapse obtained as estimated from a study of serial post-operative films; the survival of the different groups is shown in Table I. Group I

TABLE I.—Survival 5 Years after Operation according to Degree of Collapse

	Group	No.	Alive	% Alive	L.S.O.
Satisfactory	I	28	21	75	1
	II	56	50	89	1
Incomplete ineffective	III	12	7	58	—
	IV	28	19	68	—
	V	76	36	47.5	—
		200	133	66.5	2

indicates a pneumothorax in which there is complete relaxation of the apex with no adhesions to the lateral chest wall or upper mediastinum. In Group II the lung is free of the chest wall but there are adhesions to the upper mediastinum below the level of the clavicle. Several patients in these two groups had unimportant basal adhesions associated with upper-zone disease. Group III includes all cases with the lung completely freed except for adhesions to the mediastinum as far up as the apico-mediastinal angle. In Group IV the lung apex was adherent to the cupula. Group V includes those cases in which there was massive adherence of the apex to the dome of the chest and all cases in which there were inoperable adhesions to the lateral chest-wall irrespective of the apical relaxation. Before operation none of the cases had a collapse which could be classed as Group I or II.

Edwards and Lynn (1939) found that the immediate effect of pneumothorax was not impaired by undivided adhesions of the mediastinum below the level of the clavicle. From this it appears that these adhesions are also without harmful effect on the late results.

It is worthy of note that these findings are not in agreement with those of Jeanneret and Gilliard (1942), who insist for full effect the freeing of the lung must be carried as far as the hilum on the mediastinal aspect. Collapse of this nature was present in 55 of their 300 cases of pneumothorax without pneumolysis, and of these 55 cases 49 (89%) found to be efficacious after six months. In the present series it is shown in Table I that of 56 cases with mediastinal adhesions below the level of the clavicle, 50 (89%) are five years after operation. We are of the opinion that adhesions to the medial thoracic wall below the level of the clavicle are in most cases without effect on the course of the pneumothorax, and that operation in this area can often be needless and dangerous.

In cases with adhesions either to the apico-mediastinal angle (Group III) or the cupula (Group IV) the survival rate is distinctly less satisfactory. So far as deductions can be made from such small figures, it seems to us that the removal of some apical adhesions is of small benefit to the patient as the apex can be dropped below the level of the clavicle. The 76 cases with ineffective pneumothorax (Group V) survival of only 47.5% is an indication of the small therapeutic value of this type of collapse.

Since we have found the cases in Group II to have survived at least as well as Group I, both as a whole and when certain factors were controlled, we have in the subsequent tables combined the groups into a class designated "satisfactory collapse." For the same reasons Groups III and IV have been combined as "incomplete collapse."

In the "satisfactory collapse" group it was possible to follow 81 of the 84 patients for six years after operation, and more detail was available as to their present condition:

Number of patients	84
Total alive	69
Well and working	56
Unable to work	13
Dead	12
Lost sight of	3

Of the 56 who were working 52 had completed their treatment, and the other four had their disease well controlled with refills at intervals up to 10 weeks. One patient had died in the sixth year, and one had been lost sight of.

Ministry of Health Classification on Admission

The Ministry of Health classification on admission correlated with the radiological result and survival in Table II.

TABLE II.—Classification on Admission. Correlated with Degree of Collapse and Survival 5 Years after Operation

	T.B. Minus			T.B. + 1			T.B. + 2			T.B. + 3		
	No.	A	% A	No.	A	% A	No.	A	% A	No.	A	% A
Satisfactory ..	7	7	100	2	2	100	44	40	91	29	22	76
Incomplete ..	5	4	80	—	—	—	18	14	78	17	8	47
Ineffective ..	6	5	83	—	—	—	34	17	50	36	14	39
Totals ..	18	16	89	2	2	100	96	71	74	82	44	54

The survival of even 54% of T.B. + 3 patients for 5 years is not unsatisfactory. An effective pneumothorax in this same class improves this figure to 76%. The number in the T.B. + 3 group is too small to warrant any conclusions, but the survival of 16 of the 18 is in keeping with the good prognosis for patients with negative sputum after operation, which is apparent in a later table.

State of Contralateral Lung

The contralateral lung was classified as "good" when it was clear or when minimal infiltration was present, and as "bad" when there was cavitation or massive infiltration likely to progress to early cavitation. Eleven cases with ineffective artificial pneumothorax without pneumolysis on the contralateral side were included in the "bad" group. Intermediate cases were classified as "moderate." The state of the contra-

lateral lung is correlated with the radiological result of operation and survival in Table III. Of the 198 cases 93 (47%) had

TABLE III—*State of Contralateral Lung Correlated with Degree of Collapse and Survival 5 Years after Operation*

	Good			Moderate			Bad or A P

Totals	52	43	83	53	40	76	93	50	54

* 1 accidental death

advanced disease in the contralateral lung and this group accounted for 77% of all the deaths. There was no death from tuberculosis among the 26 patients with a satisfactory collapse accompanied by moderate infiltration of the contralateral lung. The survival of 74% of those with satisfactory collapse and contralateral cavitation was unexpectedly high and noteworthy. These findings support the view that control of the disease in one lung favours healing in the other.

The prognosis for the tuberculous patient with bilateral cavitation is always poor, and in our series contralateral artificial pneumothorax was either impossible or unsatisfactory. So artificial pneumothorax with pneumolysis was the most radical treatment applicable to them. A small proportion would nowadays become candidates for contralateral partial thoracoplasty, but in this class of case "many are called but few are chosen."

Sputum

Sputum was negative or absent three months after operation in 138 (70%) of the 198 patients who were followed up. Of these sputum-negative patients 109 (79%) survived five years, compared with only 40% survival in the sputum-positive group. The great majority of the negative findings were confirmed by concentration and culture.

The correlation between the state of the sputum three months after operation and the degree of collapse obtained is shown in Table IV. It is noteworthy that only one of the 65 sputum-

TABLE IV—*Sputum 3 Months after Operation Correlated with Degree of Collapse and Survival 5 Years after Operation*

	Negative			Positive		
	No	A	% A	No	A	% A
Satisfactory	65*	62	96	17	9	53

Ineffective	48	28	57.5	28	8	29
Totals	138	109	79	60	24	40

* 2 accidental deaths.

negative patients with satisfactory collapse died of pulmonary tuberculosis. In 13 of the 17 sputum-positive cases with satisfactory collapse the contralateral lung was classified as bad, and was the probable source of the positive sputum.

In the "incomplete collapse" group the survival of 76% of the sputum-negative cases suggests that a considerable number of these artificial pneumothoraces are worth maintaining, provided control of the disease is indicated by negative sputum. Of the 15 sputum-positive cases in this group only 7 survived. Since a contralateral origin for the bacilli could not be excluded in 6 of the 8 patients who are dead, we do not feel that any conclusions can be drawn from these small figures. But throughout the series the prognosis is gloomy for the patient whose sputum remains positive, and it is imperative that every other possible method of treatment should be considered. Unfortunately the hard core of untreatable cases remains distressingly large.

Altogether Table IV suggests very strongly that the achievement of a negative sputum is quite as important for the patient himself as for his contacts.

Extent of Area Cauterized

In every case the operator (P.W.E.) described the adhesions divided and estimated the area of the burnt surface of the

peripheral stumps. According to this estimate, the extent of area cauterized was classified as small when only strings and thin bands were divided, moderate, and large. Only very extensive cauterizations were included in the "large" group.

Of the 82 satisfactory collapses 66 were the result of moderate or large cauteries. The proportion of different sizes of cauteries was similar in the other two collapse groups except for a slightly greater incidence of large cauteries in the ineffective group. The size of cautery has been correlated with the radiological result of operation and survival rate in Table V. It

TABLE V—*Extent of Area Cauterized Correlated with Degree of Collapse and Survival 5 Years after Operation*

	Small			Moderate			Large		
	No	A	% A	No	A	% A	No	A	% A

Totals	39	24	61.5	126	87	69	33	22	65.5

* 2 accidental deaths

appears that in this series, size of burn did not have a significant effect on the prognosis, although Edwards and Lynn (1939) found that the incidence of effusion was higher in extensive burns and that the effusions tended to be persistent in type. The majority of the empyemata occurred in the ineffective group.

Effusions

Enough fluid to cover the dome of the diaphragm in the upright position has been classed as an effusion, and smaller amounts have been disregarded. This quantity of fluid, or more, occurred in 103 of the 198 cases followed up. In 46 of these cases the fluid disappeared in a short time without aspiration. In cases in which the fluid persisted we aimed at keeping the pleura as dry as possible, and all fluid specimens were examined by direct film and culture for tubercle bacilli and pyogenic organisms.

The survival of patients having the different types of effusion is shown in Table VI. Here it is apparent that effusions which

TABLE VI—*Effect of Effusions on Survival 5 Years after Operation*

Effusions	No	A	% A
Nil	95	63	72
Transient	46	36	73
Clear T.B.	24	15	63
Clear T.B. +	15	8	53
Tuberculous empyema	9	4	44
Mixed empyema	9	2	22

quickly clear up have no ill effect. The prognosis in cases progressing to empyema is of course bad. We found, however, that the total deaths attributable to this cause were 12, in 7 of which cases the collapse was ineffective.

Discussion

As experience of artificial pneumothorax treatment has increased, more and more tuberculosis physicians have come to accept the view, often expressed by one of us (Edwards, Ann. Repts. Cheshire Joint Sanatorium), that the result of pneumothorax depends on the efficiency of the collapse. Since the general adoption of internal pneumolysis, the standard of what constitutes an efficient collapse has become more rigid, and the aim is a complete relaxation of the lung. Hyaltested and Torming (1939) have found that their patients in whom a good pneumothorax was the result of internal pneumolysis fared at least as well as those in whom the same type of collapse was present without operation. In the present series 84 patients had satisfactory relaxation of the diseased lung as a result of internal pneumolysis. Furthermore, we have found that throughout our series the collapse obtained as the result of an extensive cauterization was no less effective than that in which smaller or fewer adhesions were divided.

In those patients on whom operation carries special risk, by reason of the anatomical character of the adhesions or the poor general condition of the subject, alternatives to artificial pneumothorax must be considered. But when contralateral

disease allows of no more radical alternative the operative risk must be accepted, for success in obtaining a satisfactory collapse carries with it some prospect of improvement in the contralateral disease. The abandonment of the pneumothorax without thoracoscopy and the maintenance of an unsatisfactory collapse are both bad practice.

Summary and Conclusions

The state of 200 cases of unilateral internal pneumolysis 5 years after operation is reported.

Of these cases 2 were lost sight of in this period. 133 (66.5%) survived 5 years. 71 (86.5%) of those cases in which a satisfactory collapse was obtained by operation survived 5 years, and 56 of these were well and working after 6 years: none of them had a satisfactory collapse before operation.

A satisfactory collapse on one side seems to have greatly improved the prospect of survival in cases with bilateral cavitation.

The persistence of positive sputum 3 months after division of adhesions indicates a poor prognosis. On the other hand, a negative sputum improves the outlook in the "incomplete" and "ineffective" collapse groups.

Tuberculous empyema, especially when secondary infection is present, is a serious complication, but it accounted for only 18% of the deaths in 5 years.

If artificial pneumothorax is employed the aim should be to obtain the most complete collapse possible by the use of internal pneumolysis.

HIGH-TONE DEAFNESS IN SCHOOL-CHILDREN SIMULATING MENTAL DEFECT

BY

MARY D. SHERIDAN, M.D., L.R.A.M.

Assistant School Medical Officer, Manchester

Some years ago, after several examinations, I certified as mentally defective a girl aged 9 who had been referred to me in school as a case of backwardness associated with speech so rudimentary that the child was practically dumb. She was said to hear normally. She came when she was called and she had every appearance of understanding simple orders and requests. I verified this by several rough tests such as calling her name loudly, ringing bells, beating an enamel bowl, clapping my hands, etc., behind her back at distances ranging from one to ten feet. She never failed to turn immediately with a bright, eager smile. Her elder sister had been a certified defective and had attended a special school. There had been no question of deafness in the older girl's case: the diagnosis appeared only too obvious. In the special school, however, with its better opportunities for individual observation and teaching, it was soon apparent that the child's general behaviour, muscular control, and handwork were vastly superior to that of her classmates, and the possibility of some unusual form of deafness was considered. She was sent to the Department of Education for the Deaf at Manchester University, where Dr. and Mrs. Ewing were conducting their first work in audiometry. The audiogram at once showed that the child possessed only "islands of hearing." She was transferred to the Royal School for the Deaf at Old Trafford, where, since her intelligence was actually of a high order, she responded most satisfactorily to Dr. and Mrs. Ewing's (1938) methods of combined lip-reading and hearing-aid methods.

This case, and a somewhat similar one, prompted me to investigate the whole subject of speech and language from the physical rather than the psychological point of view, and I

was granted the privilege of studying phonetics and audiometry in Mrs. Ewing's department at the University. As my ear became more sensitive to fine distinctions in sound, and my eyes more observant to detect slight differences in the articulatory movements of the tongue and lips, I began to distinguish innumerable sound substitutions and omissions of which I had hitherto been more or less oblivious. It was soon obvious—as every speech therapist knows—that these substitutions and omissions followed definite patterns. My problem was to discover, if possible, why the same patterns kept recurring. It occurred to me that some sort of classification according to sex, age, and intelligence would be useful for the purposes of the survey. I decided to exclude cases of "baby speech" under 5 years of age. Over a period of three years I examined the speech of some thousands of elementary-school children between the ages of 5 and 14 in London, Manchester, and Cornwall. These places were chosen because the local accents differ very widely and because facilities happened to be available to me. The investigation was later widened to include some hundreds of secondary-school children of corresponding age groups; 100 certified mental defectives; 100 blind children; and finally 100 children known, from pure-tone audiometric examination, to be suffering from impaired hearing. Examination of this last group was made possible through the kindness of Dr. J. L. Burn, the medical officer of health for Salford, who had conducted a hearing survey of his entire school population, using first a group pure-tone test and then giving an individual pure-tone test to those who failed to reach the normal level in the first test. The detailed findings of the survey are too lengthy and complicated to give here, but it gradually became apparent that defects of speech are most commonly found in mentally retarded children and in children with impaired hearing; and that, although the patterns of speech defect were very similar in the two groups, certain sound substitutions and omissions were more often associated with impaired hearing, and certain others with mental retardation. Vowel sounds were only rarely interchanged: the nasal sounds (m, n, and ng) were usually correct (although occasionally "n" would be substituted for "ng," after the manner of our "huntin'" and "fishin'" forebears); but the sounds represented in ordinary script by the letters r, l, w, and y were fairly often substituted for each other, so that a "rabbit" might be a "labbit," a "wabbit," or a "yabbit," and a "little lamb" might be a "ritter ramb" or a "yitty yamb." The sounds of "t" and "d" were often omitted, especially at the ends of words. These same sounds, which are "front stops," were very frequently substituted for the back stops, "k" and "g" (this "cup of cocoa" became "tup of toto"); but the most frequently defective sounds of all were those of "s," "f," and "th" and their voiced equivalents "z," "v," and "th" (voiced). The "s" defects included substitutions by "th" (the common "lisp"), "sh," "t," and a sort of voiceless "l" rather like the Welsh "ll" sound in the word "Llewellyn." No less than 83% of my cases in which a defect of "s" was the sole defect present were associated with malocclusion of the jaws (Seth and Guthrie (1935) give a 90% association), and the frequency with which I either observed thumb-sucking myself or obtained a history of the habit from the mothers leaves no doubt in my mind of the permanently harmful effects of this practice. The most common substitution of all in the elementary-school children, the blind children, and the mental defectives was "f" for "th" (e.g., "thirty-three things" would be "firty-free fings"). This defect did not once occur in the secondary-school group, probably because the intelligent child, even if his hearing is slightly impaired, rapidly learns to distinguish these sounds by their lip movements and by their different visual symbols in reading-books. It was not so common in the hard-of-hearing group as defects of "s" and "r," doubtless for the same reason.

It is to Dr. Harvey Fletcher (1929), the physicist employed by the Western Electric Film Co. in research on the transmission of speech sounds, that we owe the invention of the audiometer. A complete description of the chart or audiogram and how it was evolved is given in his book. Otologists have been using the audiometer to diagnose deafness for so many years that it is unnecessary to describe it here; but for the sake of those who are not familiar with the chart it may be said that the normal "speech range" extends over some 6½ octaves, from

90 to 8,000 double vibrations per second. The "pure tone" or fundamental note of middle C on the piano is 256 (on the horizontal scale), so that we use one and a half octaves below and five octaves above this note. The line 0 represents normal hearing. The figures on the vertical scale represent the intensity of sound in decibels, 10 being approximately equal to the whisper of leaves in a faint breeze, 20 a whisper at 5 feet, 30 normal conversation at 4 feet, 75 a man shouting at 4 feet, 90 a lion roaring at 18 feet, and 110 (about the limit of human endurance) a steel plate hammered by four men (R. T. Beatty, 1932).

The late Dr. Phyllis Kerridge of University College Hospital, who first introduced audiometry into this country, said that the "middle frequencies" are the most important for speech recognition (Kerridge, 1937) but Dr. and Mrs. Ewing consider that good hearing over 250 to 5,000 d.v. is necessary for accurate appreciation of speech. Harvey Fletcher was able to show that vowels are normally heard more easily than consonants, partly because their phonetic power is higher (he says the sound "aw" has a phonetic force 680 times as great as the voiceless "th") and partly because their fundamental notes are at the lower end of the scale, although the sound "ee" (as in "speed") has important harmonic components among the upper frequencies: the sounds of "l", "r", and "ng" are the easiest of the consonants to hear. The most difficult sounds are "v", "f", and "th," which together account for more than half of the mistakes made in listening to nonsense syllables. He also noted that the sounds most often affected by filtering out the high frequencies were "s", "th", "z", "t", and "f". These findings are significantly comparable with my own observations concerning the sounds most often defective in school children. In my survey I had each day noted down carefully the phonetic substitutions and omissions that came my way but did not attempt to analyse them until the entire period of review was over. In this way I tried to eliminate all my preconceived notions regarding speech defect. Subject to the limitations of my own visual and auditory fields, the results charted were as accurate as I could make them.

As noted above, it gradually became apparent that defects (or, perhaps more accurately, immaturities) of speech sounds were associated most commonly with two groups of children—those who had impaired hearing and those who were mentally retarded. The deaf child is *organically* unconscious of certain speech sounds since his auditory nerve is defective for that part of the range; the backward child is *functionally* unconscious of certain sounds although his audiogram may show no defect of hearing for pure tones. The difference between the speech and attitude of the two groups of children is difficult to describe, but it is obvious enough to the trained observer to prompt thorough investigation.

Of the various types of deafness the one most commonly mistaken for mental backwardness in school is high tone deafness. The child with impairment of low tones but good "consonant hearing" does not, in my experience, suffer a comparable educational disadvantage. He hears the vowel sounds diminished in power but normal in quality, the "speech tunes" rise and fall with their normal cadences, and provided he can sit near the teacher, his disability will scarcely be noticed unless it is severe. The child with heavy loss over the high frequencies, however, will never be able to acquire the finer consonants naturally—that is, by ear; the speech tunes will have gaps (as if he were listening to a piano in which some of the notes were dumb), and his own speech, re-echoing as all children's speech does only the sounds that are fully appreciated, will show distortions varying in proportion to his hearing loss from mere indistinctness to gross unintelligibility. Often the good vowel hearing of these children will deceive the parent, the teacher, and the medical officer so completely that they are considered to be not deaf but stupid and obstinate. Their attainments in the basic subjects, particularly spelling and dictation are seriously retarded and may be non-existent. Their attainments in arithmetic are usually less rudimentary and may be comparatively good, because it is easier to recognize numbers from vowel sounds alone, and the few visual symbols needed are soon learnt. (The acquired ability to recognize numbers from vowel sounds alone must always be remembered in using a gramo-

phone audiometer, especially with adults who are experienced listeners and whose minds are accustomed to "making up" the whole word from hearing a mere fraction of it.) It is probable that many of the cases diagnosed in the past as congenital word-deafness or auditory imperception were, in reality, examples of high-tone deafness. It must be obvious that an audiogram should be made of every child over 7 years old whose speech shows more than two phonetic substitutions or omissions, whether or not deafness has been suspected, and that no child showing speech defect, however slight it may seem to the untrained ear, should be certified as mentally defective without a complete investigation of the hearing.

I have come across several such cases in the course of the past year. The following are selected because they are particularly instructive and because I first suspected, from their speech alone, that the hearing for high tones was defective.

It may be noted that in each case the bone conduction as well as the air conduction is tested, but to prevent confusion these readings are omitted from the charts. One case of low-tone deafness is included for comparison. In every case clinical tests are also given. The tests used are 5 lists of 25 words each and groups of sentences standardized by Kerridge and Fry (1939).

Illustrative Cases

Case 4—Girl, aged 13 years 10 months. Certified as mentally defective at 11 years with a Binet I.Q. of 50. At the retest 12 months later the I.Q. was 72. The child's speech was noted as "slightly defective." (To my trained ear after I had studied phonetics it was gross.) The defect markedly involved "s," "sh," "r," and "k."

Chart of Case A

Deafness had never been suspected at home, in school, or in the clinic. The case was re-examined finally only a few weeks before the child was due to leave school. Further training until 16 was offered but refused. Re-examination some months later was offered, but no reply was received.

Case B—Girl aged 13 years 8 months. Certified at 9 years with an I.Q. of 67. (Later examinations gave 70.) The child's speech

Chart of Case B

was noted as "indistinct." It involved "s," "sh," and "r" principally. There was in this case a family history of deafness. The parents gratefully accepted the special training offered, and the child was admitted immediately to a school for the deaf, where she will remain until 16 years old, and where she will be taught a suitable trade.

Case C—Boy aged 9 Referred to the clinic by his teacher as "hopelessly backward and unteachable, with very poor speech." His speech was completely unintelligible. The defect involved most of the consonants, the back vowels "oo" (pool) and "aw" (paw)

with her back turned, she heard none of the third list of facing at 1 metre, she repeated 20 of the fourth list correct hearing for connected speech, in which the "tunes" help it is (facing) 4 out of 5 at 3 metres, and 5 out of 5 at 1 metre

Chart of Case C

were strongly nasalized. His comprehension of other people's speech was quite good, but his scholastic attainments were nil. The audiogram showed very plainly the severity of his defect. He was immediately admitted to a school for the deaf.

Case D—Boy aged 12 This was one of the most dramatic cases encountered in the research. The boy was one of a highly intelligent family of five. His speech defect markedly involved "s," "r," and "th," but his concentration was so good that, except for dictation, in which his disability caused him to appear very backward, his scholastic attainments were normal. His English composition

Chart of Case D

tion, in which he could choose his own words, was well up to standard, and his arithmetic was good. His deafness had never been suspected either at home or in school. He had merely been considered a rather mediocre member of a clever family. He has a distinct gift for drawing, and is being referred for special training in art. He is also attending the lip-reading classes provided for all these children.

Case E—Girl aged 11 This child was suspected of deafness at 3 years of age by her parents because she was "late in talking." Her defect involves "s," "sh," and "r" markedly. She is highly intelligent and has actually won a scholarship, she attends a secondary school, where her teachers, informed of her disability, have been able to give her special consideration. She is now successfully learning French. She is an expert self-taught lip-reader. At 3 metres, with her back turned, she did not hear a single word of the first list of 25. Facing the speaker at the same distance, she repeated 16 correctly out of the second list of 25 words. At 1 metre,

Chart of Case E

Case F—Girl aged 13 This chart of typical low-tone deafness is given only for comparison. There was a family history

Chart of Case F (low-tone deafness)

otosclerosis. The child's speech was perfect, but very quiet. School work was excellent.

Conclusions

The estimation of the hearing of children by pure-tone audiometric methods is highly skilled work. Every large school medical staff should possess at least one medical officer (preferably a recognized Certifying Officer already familiar with normal standards of intelligence and scholastic attainment) who is adequately trained in audiometry and phonetics. Small authorities could send their cases for investigation to the large centres.

The hearing of all children over 7 years old who show persistent defects of articulation should be investigated by the trained medical officer. The co-operation of other school medical officers, speech therapists, and teachers in referring cases is essential.

No child with persistent defective articulation should be certified as mentally defective on the results obtained from tests involving language without an investigation of the hearing.

Accurate diagnosis of high-tone deafness is already possible. The problems of its aetiology and treatment (medical and educational) are matters urgently needing consideration.

AN "EXPLOSIVE" OUTBREAK OF HAEMOLYTIC STREPTOCOCCAL TONSILLITIS ON AN R.A.F. STATION

BY

THOMAS S. WILSON, M.B.

Fl. Lieut., R.A.F.V.R.

The *Bulletin of War Medicine* of July, 1943, Vol. III, No. 11, published an abstract of an article by Bloomfield and Rantz. This described an outbreak of streptococcal sore throat in an American Army camp. The following description of an epidemic which occurred on an R.A.F. station may prove of value. It will be seen to be similar in many respects, but it presents some interesting points of comparison.

Incidence of Cases

The outbreak occurred in Nov., 1942, and of a total camp personnel of 14 officers and 351 airmen, 89 airmen were affected. The "explosive" nature of the epidemic is indicated by the daily incidence of fresh cases, which was as follows:

1st day	4	5th day	5
2nd "	42	6th "	2
3rd "	25	7th "	2
4th "	8	8th "	1

Subsequent to this, no fresh cases were reported.

Clinical Features

Clinically, the patients were acutely ill, showing marked local and general reactions. The tonsils were red and oedematous, with patches of exudate. In many cases the cervical glands were enlarged and tender. Those patients without tonsils had a diffuse pharyngitis. Temperatures ranged up to 104°.

Response to the sulphonamide group of drugs was not as dramatic as might have been hoped, and in many cases there was a recrudescence of pyrexia around the tenth day. Blood sedimentation rates were almost invariably markedly raised—in some instances as high as 85 mm. (Westergren) in 1 hour—and even after the lapse of 4 to 5 weeks an increase was observed in many cases. Convalescence tended to be prolonged, 3 to 4 weeks elapsing before discharge from hospital. Two cases of otitis media, one of acute carditis, and two of arthritis were among the complications. Throat swabs from a number of patients all gave cultures of a haemolytic streptococcus which belonged to Group A Lancefield and was serologically Type 9.

Investigation

In the course of investigation it was noted that the cases were confined entirely to those who dined in one particular mess. Of the officers, N.A.A.F.I. personnel, or civilians (none of whom fed in this mess) none was affected. There was no relation between the case incidence and the distribution of personnel in the sleeping billets. These features suggested a food-borne infection rather than the more usual "droplet" spread from case to case, although it is probable that the 10 cases occurring from the fifth to the eighth day were infected in this fashion. By studying the movements of affected personnel immediately before the outbreak, the period when the infection was presumed to have occurred was narrowed down to between 2 and 3 days prior to the first case being seen. Bacteriological examination of food-handlers was carried out. It was discovered that a cook who had been in charge of the preparation of milk on one of the days under suspicion was heavily infected with haemolytic streptococci. These were of the same serological strain as those isolated from patients, although the cook was himself symptom-free. The milk in question was tinned, and was prepared 2 to 3 hours before use by mixing one part of tinned milk with two parts of boiling water. This would give the mixture an initial temperature of about 65 to 70° C. When it was allowed to stand this would rapidly drop, providing an excellent medium for growth of organisms at optimum temperature. During the period in question the cook was suffering from a severe head cold and was sneezing continually. The conclusive proof of isolating the organisms from the milk under suspicion was impossible, as a sample was not available. Circumstantial evidence, however, strongly supports the assumption that this was the medium by which the infection was spread.

Carrier Rate

With regard to the "cookhouse" personnel, the following statistics were obtained when throat swabs were taken 12 days after the outbreak: 20% had developed acute tonsillitis; 45% were carriers of haemolytic streptococci (30% Group A Type 9, 15% not Group A) and symptom-free; 35% had negative throat swabs and were symptom-free. If it is permissible to consider these persons as a representative cross-section of the community (the approximate similarity between the percentages who actually developed the condition would seem to support this assumption)—20% of the cookhouse personnel and 25% of the station personnel, it can be concluded that 12 days after the outbreak of the epidemic 45% of the community were carriers of haemolytic streptococci. In 30% of cases the organism belonged to Group A Type 9.

After the lapse of a further 12 days, swabbing of the throats of a number of personnel chosen at random showed that the haemolytic streptococcus carrier rate had fallen to 25%. Unfortunately grouping and typing of this further series of throat swabs was not carried out, but it is probable, however, that this decline of 20% occurred in the numbers of those who harboured haemolytic streptococcus Group A Type 9.

Presuming that the decline in carrier rate during the first 12 days subsequent to the outbreak was approximately the same as that during the second 12 days (in all probability it was even greater), it would appear that on the first day of the epidemic the proportion of personnel who harboured this particular strain of organism in their throats but were symptom-free (i.e., were immune) would have been in the region of 50%.

In the intervening period between the two series of throat swabs the community had been divided into two sections, which were isolated from one another. The personnel of one section carried out gargling with pot. chlor. and phenol twice daily, while among those of the other section no preventive measures were taken. It was noted that, in spite of this, the carrier rates of the two sections remained exactly the same. This would seem to substantiate the doubts which have been cast on the usefulness of gargling in an outbreak of this kind.

Conclusion

It is concluded that this was an epidemic in which the infection was primarily food-borne, with case-to-case spread playing a very minor part. It is thought that the reason for the comparatively small incidence of case-to-case infection may have been the fact that those susceptible had been picked out by the primary infecting agent, the few who escaped this hazard rapidly succumbing to "droplet infection." This is borne out by the remarkably large number of immunes—probably at least 50% of the community.

Comparison with a Similar Outbreak

On comparing this epidemic with that described by Bloomfield and Rantz the following will be noted: (a) That in both cases a food-borne infection was suspected. (b) That in both instances case-to-case infection was minimal: while in the latter this was presumed to be due to a low virulence of the infecting organism, in the former the reason was thought to be that the majority of those who escaped were immune to the particular strain concerned. (c) That the causal organism in the American epidemic was of a different Griffith subtype, being Group A Lancefield subtype 15. (d) That the main clinical features were similar in both, with the exception that Bloomfield and Rantz describe the appearance of a characteristic scarlatiniform rash with subsequent desquamation in one-fourth of the cases, while in no instance was a rash observed in the present epidemic. This suggests that haemolytic streptococci belonging to subtype 9 play no part in the causation of scarlet fever, in contradistinction with those belonging to subtype 15.

Summary

An explosive outbreak of haemolytic streptococcal tonsillitis is described.

The evidence suggested that it was a food-borne infection, probably by contamination of milk by an infected cook, who was a carrier.

A large proportion of the community were immune to this particular strain of organism.

Routine gargling had no effect in reducing the carrier rate during the epidemic.

A comparison is made with a similar type of outbreak which occurred in an American Army camp.

I wish to tender thanks to Dr. N. Crowley for the help she gave me in the bacteriological investigation of throat swabs, etc.

TREATMENT OF RHEUMATOID ARTHRITIS WITH BISMUTH

BY

A. H. DOUTHWAITE, M.D., F.R.C.P.

Physician to Guy's Hospital

The use of gold against active rheumatoid arthritis has fully justified itself in spite of the faulty premises which led to its introduction. Analysis of my last 200 cases indicates that it results in the disappearance of symptoms and signs of activity in 70%, but relapse within six months occurs in the majority of those subjected to only one course of injections—usually 0.8 g. Four courses in two years appear to eradicate the disease in 55%, but the possibility of recurrence, even 15 years later, forbids the use of the word "cure." The great objection to gold treatment is the high incidence of toxic reactions. In the early days it was as much as 45%, but with decreased dosage, and the use of the less toxic calcium aurothiomalate, the figure has fallen to 10 in the last 60 arthritides so treated—i.e., approximately 16%. Immediate interruption of treatment at the first sign of any one of the numerous reactions which may arise will almost invariably be followed by a slow but complete disappearance of the toxic effect. I have seen one case of agranulocytosis recover after five months, and one of gold nephrosis with oedema recover after three months. In each case instructions as to dosage, choice of preparation, and watch for toxic signs had not been observed. The commonest and most persistent reaction is seen in the skin, in which various irritating rashes are produced. It is this which has led to such fear of gold.

It seems probable that gold acts by virtue of its being a heavy metal, and not from any specific effect on the infecting agent responsible for the arthritis. In order to see whether it were possible to obtain the same effect with a less toxic substance, I started, late in 1942, administering bismuth. This substance was chosen because pharmacologically it acts similarly to heavy metals, it is easily procurable in injectable form, and its toxicity is low.

Method

Twelve consecutive patients with active rheumatoid arthritis were treated with weekly intramuscular injections of injectio bismuthi (9) or injectio bismuthi salicylatis (3). One mil of the former and 2 mils of the latter contain 0.2 g. of bismuth and bismuth salicylate respectively. These quantities were used for 10 injections, giving a course-dose of 2 g.

Clinical Material.—Ten females, two males; aged from 24 to 63 years. With the exception of one who had suffered for 9 years, they gave histories of 9 years (2), 8 (2), 4 (4), 2 (1), 1 year (1), 1/2 year (1). Eleven patients had had one or more courses of gold in the past; in three only had it failed to do any good. The others had relapsed, usually within 6 months of finishing the course.

Signs of Activity.—In all cases there were pain and swelling of many joints, a recent extension of the disease to joints previously spared, and a raised E.S.R. in one hour the figure (Westergren method) were 22 mm. to 100 mm.

Results

The effect of treatment was classified as—

Group 1—Very good if at the end of the course pain and swelling (not due to old deformity) had disappeared, and if the E.S.R. was below 7 mm for one hour. Only four patients qualified for this category, the initial and final E.S.R. figures being 22/2, 23/5, 70/5, 23/5.

Group 2—Good was the classification of those patients whose clinical signs had improved as in the former group but in whom the final E.S.R. for the first hour was between 7 and 15 mm. There were two of these with E.S.R. figures of 52/11 and 50/11.

Group 3.—Moderate improvement: those patients whose pain decreased and whose ability to perform certain movements—e.g. making a fist and walking—improved beyond doubt. Two fell into this category, with a noteworthy inertia of sedimentation rate. The initial and final figures were 40/22, 35/49.

Group 4.—Failure—i.e., those arthritides whose symptoms and signs showed no improvement. Of these there were four. The corresponding E.S.R. figures were 55/34, 38/35, 31/26, 100/110.

None of the patients has been under observation for less than 9 months or more than 1½ years from the beginning of bismuth treatment.

For practical purposes Groups 1 and 2 may be taken together as showing good results and Groups 3 and 4 as being failures. This gives improvement in half of a small series. There was no relation between the duration of the disease and the age of the patient with regard to the effect, or absence of effect, of bismuth on the activity of the arthritis. The two males were failures. Three patients who had had gold previously and obtained no relief provided three bismuth failures.

Relapses.—In Group 1 there has been no relapse. In Group 2 both have relapsed within 2 months of the end of treatment. In Group 3 both members relapsed within 7 weeks.

Toxicity.—There were no toxic reactions.

Difference of Preparation.—Bismuth salicylate provided two failures and one good result. It is probably immaterial whether bismuth or the salicylate is employed. The bulk of the former is less.

Control.—Six rheumatoid arthritides were given weekly intramuscular injections of 1 mil of sterile water. At the end of six weeks this was stopped because no objective improvement was seen, and in only one case did the patient declare herself to suffer less pain.

Conclusion

(1) Bismuth by intramuscular injection appears to be capable of exerting a beneficial influence on the course of rheumatoid arthritis. (2) It compares unfavourably with gold in this respect, the probability of lasting benefit being less than half that expected from gold. (3) Relapse appears to occur more quickly than that following gold. (4) Gold-resistant arthritis are unlikely to benefit from bismuth.

Bismuth is indicated only for rheumatoid arthritides who show intolerance, whether physical or mental, to gold.

Medical Memoranda

Trypanosomiasis in a European treated with Pentamidine

As cases of early trypanosomiasis may occasionally be seen at the present time among Europeans returning from tropical Africa, an account of the treatment of such a case with 4,4'-diamino-diphenoxypentane (pentamidine, or M & B 800) is topical. An extensive trial of this drug on natives in Uganda was reported by Lawson (1942), and a fatality, possibly attributable to it, by McComas and Martin (1944).

CASE HISTORY

The patient, a Polish officer aged 32, had been stationed in a tsetse-fly area in Sierra Leone from April, 1942, to May, 1943. He thinks that he was bitten several times, but remembers particularly an occasion in Jan., 1943, when he had what he took to be a tsetse fly inside his trousers. Apart from malaria he was well until May, 1943, when he had a brief attack of pain and swelling of the glands in the neck, axillae, and groins. In June, 1943, he returned to the United Kingdom, and noticed occasional headaches, fever, and swelling of the face in the mornings. In the middle of September he reported sick with what he thought was malaria; scanty trypanosomes were found in thick blood films, and he was admitted to a military centre for tropical diseases.

Examination revealed the following: Irregular pyrexia to 100.5°, pulse rate almost constantly 100 to 110 a minute; mental state apparently normal; puffy swelling of lower eyelids and adjacent face, slight enlargement of occipital, axillary, and inguinal glands; no rash; spleen not palpable. A blood count showed: red cells, 3.7 millions per c mm; haemoglobin, 78%; white cells, 12,500 per c mm—neutrophils 70%, eosinophils 5%, monocytes 4%, lymphocytes 21%. Very scanty rings of *Plasmodium falciparum* were found in thick blood films, and, on two occasions, scanty trypanosomes in blood films and in juice from a cervical gland.

Treatment was begun in Sept., 1943, with 100 mg of pentamidine dissolved in 5 c cm of sterile distilled water, given intravenously.

on two successive days, followed by eight daily injections of 150 mg. After five days without treatment a further injection of 200 mg. was given, followed by nine more, each of 300 mg., over a period of 14 days. A total dose of 4.3 g. was thus given in 39 days to a patient weighing 128 lb. As the preparation used was the relatively soluble isothionate, this would probably correspond to a dose of about 3 g. of the preparation given by Lawson (1942). The solutions were freshly prepared and the injections were given very slowly, as they were accompanied by distressing palpitation, a sense of pressure in the forehead, and itching of the skin. The blood pressure was taken on several occasions, and no fall was noticed after the injection. There was no thrombosis of veins or local reaction at the site of injection. The urine remained normal throughout the treatment.

Rapid improvement followed the first few injections. The temperature and pulse rate fell to normal, the headaches and swelling of the face disappeared, and the weight increased. When last seen the patient felt perfectly well in every respect. No enlarged glands could be felt.

The erythrocyte sedimentation rate, which had been 81 mm. in one hour and 114 mm. in two hours before treatment, was 22 mm. in one hour and 54 mm. in two hours at the end of treatment, and 5 mm. in one hour and 15 mm. in two hours three months later.

The blood count at the end of the treatment was: red cells, 4.6 millions per c.mm.; haemoglobin, 95%; white cells, 9,000 per c.mm.—polymorphs 61%, eosinophils 2%, basophils 1%, lymphocytes 32%, monocytes 4%. No trypanosomes were found. It is noticeable that no leucopenia had been produced and that the figure for red cells and haemoglobin had substantially improved, although no drug but pentamidine had been given.

No trypanosomes were found in the cerebrospinal fluid. The changes in this fluid, with treatment, are shown in the following table:

	Total Protein (mg.)	Cells per c.mm.	Nonne	Pandy
Before treatment	35	10	+	+
After treatment	45	22	W+	+
Three months later	30	4	Tr	Tr

	Lange	Takata-Ara (minutes)							
		0	3	8	10	30	60	90	
Before treatment	3334432100	Tr	W+	W+	W+	+	+	+	+
After treatment	2211110000	0	Tr	W+	+	+	+	+	+
After three months	112232100	0	FTr	Tr	+	W+	W+	W+	+

Positive (+). Weak positive (W+). Trace (Tr). Faint Trace (FTr). Doubtful (=).

I am indebted to Dr. H. H. Fleischhacker for these observations and for the opinion that, though their exact interpretation is uncertain (Fleischhacker, 1943), they probably indicate a diminution in the globulin fraction of the protein and a return of the cerebrospinal fluid towards normal.

In view of the apparently satisfactory results of treatment with pentamidine in this case, the patient was allowed to return to duty without further treatment, and was advised to have his C.S.F. re-examined in six months' time.

I am grateful to Col. C. F. Anthonisz, Officer Commanding a Military Hospital, for permission to publish this case report and to Messrs. May and Baker for supplies of pentamidine.

R. R. BOMFORD, D.M., F.R.C.P.,
Lieut.-Col., R.A.M.C.: Officer in Charge of a Medical
Division at a Military Hospital.

Spontaneous Thrombosis of Axillary Vein

The condition reported below is not common, only two or three cases a year being seen at a big general hospital.

CASE HISTORY

On Feb. 2, 1944, the patient, an airman, was first seen. He complained of a sudden diffuse swelling of his left arm, which had begun 24 hours before; on rising on Feb. 1 his left arm was swollen from finger-tips to above the elbow and was painful along the inner side of the upper arm. He did not recall any recent trauma to arm or shoulder; he had had no infection of the hand or arm and no other symptom previous to the swelling. He was employed on cook-house duties with no exceptionally hard work; he was, however, in the habit of reaching for boxes and jars from high shelves.

On examination the patient was a well-developed young man aged 22. There was a diffuse cyanotic swelling of his left arm, forearm, and hand, including the fingers; pitting oedema was present only to a very slight extent. There was tenderness over the third part of the axillary artery extending downwards for three inches. The ante-cubital veins and those on the dorsum of the hand were much distended with blood, and the whole limb gave the impression of being taut. There was a small scratch on the anterior surface of the forearm, which showed no evidence of infection; no tenderness of the epitrochlear or axillary lymph glands was found. The subclavian, brachial, and radial pulses were all present, though the left radial

was weaker than the right. Elevation of the arm for purposes of testing for cervical rib or other pressure on the subclavian vessels was not attempted at this stage. General examination revealed nothing abnormal. The temperature was not raised.

Progress under Treatment.—The patient was placed in bed on his back, with the left arm raised on two pillows and immobilized between sandbags. Next day the temperature rose to 99.6° F.; the swelling was more obvious, had become very firm, and he was complaining of tingling in the finger-tips; examination revealed no sensory changes in the arm or hand. The patient was given prophylactic sulphathiazole 2 g. stat., then 1 g. four-hourly. On the fifth day the firm oedema had much increased, particularly in the region of the elbow-joint, and there was a cord-like thickening and tenderness along the line of the brachial neurovascular bundle. On the following day the temperature returned to normal and the swelling had started to diminish: the sulphathiazole was stopped, a total of 13 g. having been given. On the eighth day the symptoms had greatly lessened and there was no pain or paraesthesiae. He was allowed up, and was discharged to his unit for 14 days' sick-leave. Besides the chemotherapy, the treatment consisted of daily applications of glycerin and ichthylol paste to the upper arm.

On return from leave he was examined for evidence of cervical rib, scalenus anticus syndrome, and subclavian aneurysm, but there was no evidence of these. Radiographs revealed no abnormality in the base of the neck and the Wassermann test was negative. A diagnosis of spontaneous traumatic thrombosis of the axillary vein was made, probably resulting from sudden rupture of the small veins draining into the axillary in the region of the bicipital groove, after stretching of the arm upwards as in reaching for an article from a high shelf.

DISCUSSION

The aetiology of axillary vein thrombosis is varied, being divided into two main groups: (a) pressure mechanism; (b) tearing mechanism.

Into the first group we can put the following: (i) Pressure on the axillary vein caused by an aneurysm of the third part of the subclavian artery; this may be either a traumatic or a syphilitic aneurysm. (ii) Aneurysm of the axillary artery, caused by falls on the outstretched arm or trauma from fractures. (iii) Continuous pressure by a cervical rib.

Into the second group falls the following: If the smaller veins of the axillary region are inadequately supported by the surrounding muscles at the moment of sudden stretch they may rupture and thrombose: this thrombosis may spread up the larger veins into the axillary vein, and cause a solid block to the venous return from the arm. The temperature recorded is thought to be due to the breaking down and absorption of the thrombus. I have seen a case illustrating the above in a youth who ruptured his axillary vein, with consequent thrombosis, when about to make a violent service at tennis; he was right-handed, and ruptured his right axillary vein.

I am indebted to Squad. Ldr. Rouillard for his treatment and for comments on this case.

Fl. Lieut., R.A.F.V.R.

An Extraperitoneal Hernia of an Old Appendix Scar

The following unusual case is interesting enough to warrant publication:

Fourteen years ago Mrs. V., aged 32, of Dutch nationality, had had her appendix removed abroad. Till lately she had had no further trouble. She had come to this country at the beginning of the war, and was doing office work. Some three weeks before I saw her she began to have acute pains in the region over her appendix wound. Examination revealed a small swelling over the site of the appendix wound which seemed to be expansile on straining. On palpation this was acutely tender. It was taken to be a small bulge due to the weakness of the old scar—in other words, the start of a ventral hernia. She was advised to have the condition put right before it grew larger.

The operation was performed on Nov. 7, 1943, when a rare and curious condition was found. The scar in the tendinous portion of the external oblique muscle was good and firm, but at one point there was a small hole not more than a quarter of an inch across. Through this had protruded the extraperitoneal fat and vessels, but there was no peritoneal sac. It was the exact reproduction of the hernia met with near the linea alba where the vessels and nerves come to the surface. Though the neck of the protrusion was small, it mushroomed out to the size of a large flattened cherry, and this was the swelling previously felt. What nerves were included it was impossible to say, but it is supposed that the acute pain in the hernia of the linea alba is due to the nipping of the nerve which is always present. It is known, however, that the extraperitoneal tissue is intensely sensitive. The neck of the protrusion was closely connected and continuous with the tendon of the external oblique muscle, and had to be freed all round; it was opened and examined before being replaced and the hole closed. The patient's recovery was uneventful.

Reviews

ULCERATIVE COLITIS

The Modern Management of Colitis. By J. Arnold Bergen, M.D., M.S., F.A.C.P. (Pp. 322; illustrated, \$7.00 post paid, or 38s. 6d.) Springfield and Baltimore: Charles C. Thomas; London: Baillière, Tindall and Cox. 1943.

Dr. J. Arnold Bergen has for many years been chief of the section on intestinal diseases in the division of medicine at the Mayo Clinic. As about 250 cases of ulcerative colitis enter the clinic each year, his unique experience entitles him to speak with authority on the disease. Though his book, *The Modern Management of Colitis*, contains much of interest it is on the whole disappointing. Ulcerative colitis is classified into nine "types": (1) the common form of the disease, to which he has given the name "thrombo-ulcerative colitis"; (2) "segmental ulcerative colitis," in which the rectum escapes; (3) "chronic ulcerative colitis," which includes several unrelated groups of cases differing in various respects from the common type; (4) "tuberculous ulcerative colitis"; (5) "amoebic ulcerative colitis"; (6) colitis caused by dietary insufficiency; (7) ulcerative proctitis caused by the virus of venereal lymphogranuloma; (8) cases in which "allergy plays a role in the progress and possibly also in the inception of the infection"; (9) chronic ulcerative colitis following bacillary dysentery. But Nos. 4, 5, and 7 cannot be regarded as forms of ulcerative colitis at all, and it is doubtful whether either No. 6 or No. 8 exists as an independent condition, though food deficiency and allergy may occasionally aggravate already existing ulcerative colitis.

Bergen still believes that the diplostreptococcus he described some years ago is the cause of the common form of ulcerative colitis, though almost all bacteriologists consider it to be nothing more than a non-pathogenic enterococcus. His enthusiasm for treatment by vaccine and sera made from it appears to be less than it was at one time.

The important work of Hale-White, Saundby, Hawkins, and Lockhart-Mummery in England, Mathieu and Roux in France, and Adolf Schmidt in Germany is completely ignored in Bergen's historical survey of ulcerative colitis, from which it would appear that there was no advance in our knowledge of the subject between the original description by Wilks and Moxon in 1875 and a paper by Logan in 1919.

There is a good account of the irritable colon, though this has nothing to do with colitis, but the statement that "the associated nervous symptoms have included hysteria, introspection, fear, anger, hypochondria, neurasthenia, melancholia, unhappiness, and sorrow" shows some confusion of thought. It is also disconcerting to find an illustration representing "the average position of the large intestine with reference to the costal arch," which might have been a reproduction from an anatomy book of 1900, for it shows a colon as wide as the caecum throughout its length, with the transverse colon passing in a straight line from the hepatic flexure to the splenic flexure, and then up in the epigastrium.

HISTORY OF CAESAREAN SECTION

Caesarean Section. The History and Development of the Operation from Earliest Times. By J. H. Young, M.B., Ch.B. (Pp. 254, 16s.) London: H. K. Lewis and Co. 1944.

This interesting volume is probably the most complete history of the operation ever written, and shows that Caesarean section is one of the oldest operations in the history of medicine, its origin being lost in the mists of antiquity. Certainly it was known to the Jews as early as 140 B.C., and some of the mothers seem to have survived, for it is stated that "it is not necessary for the woman to observe the days of purification after the removal of a child through the parietes of the abdomen." There is, however, no definite evidence that the operation was ever successfully performed upon a living European woman until the year 1500, and in the British Isles the first Caesarean section from which the mother survived seems to have been done by an illiterate Irish midwife in 1738. In England the first

successful case does not appear until 1796. Many records are quoted of cases in which impatient and ignorant women performed the operation upon themselves; and up to 1888 six cases are mentioned with five recoveries!

All this, together with the arguments for and against Caesarean section as opposed to craniotomy, makes good reading, but the chief value of the book lies in the fact that the various improvements in operative technique are carefully traced. In these chapters the extraordinary fact emerges that, although suture of the abdominal wound had been practised for generations, suture of the uterine incision was not generally considered until about the year 1840, and did not become universally accepted until Sanger described his operation in 1882. We find also that the "modern" lower segment operation dates back to 1786 and, as Prof. Miles Phillips states in the foreword, "Any obstetrician proposing to modify the operation in any particular should consult this work."

War economy in book manufacture probably prevented the inclusion of illustrations, but in spite of their absence the volume is absorbing and instructive throughout. An idea of the amount of work involved in compiling it can be obtained by studying the bibliography at the end of each chapter, and we hope that Dr. Young's thesis will have the success it deserves.

A HOUSE-SURGEON'S HANDBOOK

The Hospital Care of the Surgical Patient. A Surgeon's Handbook. By George Crile jun., M.D., and Franklin L. Shively jun., M.D. Foreword by Evarts A. Graham, M.D. (Pp. 184; illustrated, 14s. or \$2.50.) Springfield and Baltimore: Charles C. Thomas; London: Baillière, Tindall and Cox.

The change from the empirical to the scientific approach in the problems of post-operative care which has occurred in the past twenty years is well demonstrated in this small book by George Crile jun. and Franklin Shively, both attached to the Cleveland Clinic. As Evarts Graham says in the foreword, it is particularly fitting that such a book should have as one of its authors the son of a pioneer in the use of physiological methods for the study of surgical problems. Its primary aim is to act as a guide to the interns working at the clinic, so that it gives a complete picture of the various methods of pre- and post-operative care which have become standardized at Cleveland.

The first section deals with physiological principles, and covers such subjects as the water and chloride balance, acidosis and alkalosis, the use of glucose and saline, and so on. The next section describes the treatment of the common post-operative complications, and there are some valuable common-sense paragraphs upon the preparation of the patient for operation. A further section gives a clear account of the technique of the procedures which the house officer may be called upon to perform frequently, including lumbar puncture, blood transfusion, thoracentesis, and gastric and intestinal intubation. Finally there is an unusual section which gives good advice to the intern regarding his relationship to patients and relatives, to the nursing staff, and to his chief.

There are clear line-drawings to illustrate many of the points mentioned in the text; and handy lists of doses of common drugs, of gastric diets, and of normal blood chemistry are provided at the end of the book. This is a useful volume which a newly appointed house officer would find of considerable value in his early encounters with surgical patients.

Notes on Books

A cheaper edition has been made of Mr. C. J. FERRÉ's book *The Soya Bean and the New Soya Flour* (William Heinemann) 3s. 6d.), published fifteen years ago and now reissued without alteration. For some unknown reason soya has not as yet become popular in the United Kingdom, though the wonderful properties of this bean for nutritional and industrial purposes have become widely recognized in other countries, such as the U.S.A. and Germany. A good description of the cultivation and varieties of the bean is given together with an analysis of its constituents, but the book mainly deals with the nutritional value of soya. The different processes of manufacturing soya flour are described, and a number of useful recipes incorporating it are included at the end of the book, which is the work of a man who knows his subject.

MERSALYL B.D.H.

In addition to its general use in early nephritis, nephroses, hepatic ascites and cardiac œdema, Mersalyl B.D.H. may be used also in the treatment of polyserositis, eclampsia (in the absence of acute pyelonephritis), Ménière's disease, obesity, thrombophlebitis and the œdema of toxic goitre.

It is probable that the diuretic potency of Mersalyl is inseparable from some degree of toxicity. Reactions are comparatively rare, however, and the beneficial effects of the use of Mersalyl are such that the few reactions reported are "*not an indication to withhold the drug but rather to use care in administering it.*" (Lancet, May 8th, 1943, p. 576).

For intravenous or intramuscular injection —

Ampoules of Mersalyl B.D.H. (Injection of Mersalyl B.P.)

For oral administration —

Tablets of Mersalyl B.D.H. (Mersalyl B.P., 0.08 grm., with theophylline 0.04 grm.)

For rectal administration —

Suppositories of Mersalyl B.D.H. (Mersalyl B.P., 0.4 grm. with theophylline 0.2 grm.)

Details of dosage and other relevant information will be gladly supplied on request.

Calorific Value	104 per oz.

'TABLOID'

'OXYLAN' DIPHENAN

for the treatment of threadworm infestation

'Oxylan' brand Diphenan (*p*-benzylphenyl carbamate) is an anthelmintic of proved efficiency in oxyuriasis. It is not merely a vermifuge, but by its toxic effect on the parasites, inhibits their reproduction. Reinfection is thus minimised since ova are no longer deposited in the anal folds.

'Oxylan' brand Diphenan is well tolerated by

both children and adults, and is free from undesirable side effects. The usual course for adults and children over ten years is one to two products three times a day for one week, with aperients. In persistent cases it may be repeated after seven to ten days. Proportionately smaller doses may be given to children under ten years of age.

Compressed products, each containing $7\frac{1}{2}$ grains. Bottles of 20, 4s. 0d. (Purchase Tax 6d. extra).
Bottles of 100, 18s. 0d. (Purchase Tax 2s. 3d. extra). Subject to Medical Discount

HEPATITIS AFTER TRANSFUSION

Transfusion of whole blood has never been a procedure entirely free from risks. Reported mortality figures from the operation have varied in different series from 0.1 to 1%. Death has usually been due to renal failure after haemolytic crises or to heart failure from circulatory overloading. Less severe reactions—haemolytic, pyrogenic, and allergic—and non-fatal vascular accidents also occur. The administration of blood products—plasma and serum—is not attended, other than in exceptional circumstances, by haemolytic reactions; but the other above-mentioned dangers remain. Another transfusion hazard is now being reported and must be seriously considered. Hepatitis is occurring after the use of certain batches of human serum and plasma. This danger was anticipated by the Ministry of Health, whose medical officers a year ago published a memorandum¹ on this "homologous serum jaundice." Up till then the condition had been recognized chiefly after yellow-fever vaccination, the virus being suspended in human serum. Such reports had come from this country,² South America,³ and the U.S.A.⁴ Hepatitis was also known to occur after the injection of serum from a measles convalescent, and, latterly, also after the injection of plasma from a mumps convalescent.⁵ In the last year the condition has been seen, and in some cases reported, after transfusion of serum and plasma.^{6,7} Bradley, Loutit, and Maunsell make a further contribution to this story in our present issue.

In one or two instances jaundice after transfusion of blood alone has been seen.⁸ It is, however, more difficult to be certain of the diagnosis in such cases. Batches of plasma and serum can be incriminated because multiple cases occur after their use; more or less homogeneous material has been given to many recipients. This does not obtain with whole-blood transfusion, which is a much more individual affair. Unless a single donor's blood on repeated occasions results in jaundice of the recipient, it is impossible categorically to aver that his blood carries a hepatotoxic agent; such a donor has not yet been reported. If he does exist—and he probably does—then his plasma or serum could easily make a large pool icterogenic. Very small quantities even of pooled material are effective, though the dose and route of administration seem to bear no relation to the severity of the resulting hepatitis.

This homologous serum jaundice is probably closely related to post-arsphenamine jaundice, also very prevalent at present. Contamination of syringes with human material from previous use has been suggested as the cause of this.⁹ Its relation to infective hepatitis is less clear. There is some evidence that an attack of homologous serum jaundice or post-arsphenamine jaundice confers no immunity to infective hepatitis, and vice versa.¹⁰ The cause of homologous serum jaundice is therefore unknown. A virus aetiology has been postulated: MacCallum and Bauer¹¹ conclude from their experiments that the evidence "is not inconsistent with the view that the agent is capable of multiplying in tissue culture."

Although series of cases are now being published, the cause of jaundice must have been misinterpreted in many more. The latent period before the onset of jaundice and the accompanying symptoms is long—40 to 160 days; thus the connexion with previous transfusion may be missed. The clinical picture and the biochemical findings are usually indistinguishable from those of infective hepatitis. Most of the cases occurring may well be masquerading under this diagnosis. Although, like infective hepatitis, the condition is usually mild and of short duration, there is an impression that the mortality is higher: for example, among about 200 probable cases, not including yellow-fever-vaccine jaundice, there have been 13 deaths. In most of the transfusion cases, in contradistinction to the vaccine and convalescent-serum cases, it has been difficult or impossible to ascertain the batch of serum or plasma responsible for the condition. This is mainly because the batch and index numbers of the materials used have not been entered on the patient's case sheet. As yet, human serum and plasma processed for transfusion are not covered by the Therapeutic Substances Act, the terms of which would require such details to be recorded. As soon as the war is over steps will have to be taken to bring such transfusion materials within the scope of the Act. In the meanwhile much can be done to prevent the widespread distribution of incriminated batches. Due caution should be observed as regards the transfusion of serum or plasma; if available, blood should be given rather than serum or plasma, and unless there are strong indications for the latter (e.g., haemoconcentration). So far as possible any one case should be transfused with serum or plasma from one batch only; careful records of batch and index numbers of material given should be kept voluntarily by medical officers performing transfusions; and a follow-up should be made for at least 4 months on all cases transfused. The appointment for each hospital or group of hospitals of a full-time transfusion officer, whose duties would include the keeping of the records and the supervision of the follow-up, would facilitate this process. When hepatitis cases are discovered through the follow-up they should be notified to the Regional Transfusion Officer, together with the index numbers of the blood, serum, or plasma given. In this way the Regional Transfusion Officer would be able to arrange for the removal from circulation of icterogenic batches.

CHANGING FOOD HABITS

The science of nutrition has its essential roots in biochemistry and physiology. For the detection and characterization of diseases due to malnutrition a knowledge of pathology is necessary, while the all-round nutrition expert must also be well informed on the agricultural and economic aspects of the production of foodstuffs. So far as animals are concerned the problems to be solved will usually be confined to these four subjects. In human beings, however, complications arise in the fields of sociology and psychology. The mysteries of the kitchen must be explored, and all the fads and fancies of cooking and eating must be taken into account. In recognition of the importance of the "human element" in dietetics the U.S.A. National Research Council has not been content with setting up a committee on the biochemical and physiological sides of nutrition, but in addition has established a Committee on Food Habits whose interests are psychological and cultural. A report of this committee for 1941-3, consisting mainly of a collection of articles by different authors, is now available.¹ Its conclusions are of interest not only in giving an idea of the present state of nutrition in America but also in indicating psychological factors which must operate in various forms throughout the world.

As Kurt Lewis points out, certain foods highly prized by some are less appreciated by others. But this of course we knew from the experience of Mr. and Mrs. Jack Sprat. But to take a case more easily verifiable, the population of the U.S.A. would hardly be tempted to eat live grasshoppers, though these are eaten with relish in some less highly civilized communities. It is clear that "likes" and "dislikes" are conditioned by numerous factors. Some meals and dishes may have such traditional and sentimental associations as to become almost a form of art or folk-lore. Thus "the roast beef of old England" was praised as the food for John Bull in Napoleonic times, and long before then the foreign visitor to this country was impressed by the fact that the English peasant ate much more meat than the peasant on the Continent. Food served with speeches and gold plate at a Lord Mayor's banquet, or with hard words and enamel ware in a convict's cell, forms part of a ritual of pleasure or of pain.

A dietitian who seeks to improve the food habits of a population must therefore know not only what foods are¹ but also what foods will be psychologically acceptable. Lewin regards price, health-giving properties, satisfying capacity, taste, and social desirability as the main factors in deciding what foods shall be bought. From questioning a large group of people he concludes that in America fowl is easily the most popular meat for social occasions, with roast joints a close second favourite. Steak and chops are much appreciated for taste, whereas when money is short the best purchases are thought to be glandular meat, such as kidney and liver, and chopped

meat. In choosing from this wealth of plenty the American housewife is inclined to be more fastidious than her English counterpart and objects to the smell of kidneys during cooking. Propaganda is therefore suggested to indicate ways by which kidneys may be cooked without undue smell and to emphasize the relatively high social status of kidney in the English kitchen—one up for English cooking, for a change.

Another inquiry was made into the "meal patterns" prevalent in the U.S.A. In every country certain foods are preferred at different times of the day. Thus in England a meal of porridge, bacon and egg, toast and marmalade, with tea or coffee, could not be mistaken for anything but breakfast; on the Continent this suffers somewhat from being translated into "ham and eggs." In America cereals, eggs, bread, toast, coffee, and tea are the main breakfast foods: the more well-to-do usually include fruit, but no mention is made of bacon. So the conjunction of bacon for breakfast does not constitute a natural law! Luncheon often consists of salads, sandwiches, and "left-overs." Dinner is the main meal, and meat, potatoes, vegetables, and pudding are the most popular items. Salads are eaten at dinner more often by the rich than by the poor, but with bread-and-butter the situation is reversed.

Natalie Joffe observes that these "meal patterns" are varied among "subcultures" of the population of the U.S.A. who to some degree retain their European tastes and traditions. The Italians, who like their food to be colourful, go for cheese of the gorgonzola type, and readily eat raw vegetables so long as plenty of salad oil is available. They have a cycle of foods to be served throughout the week, including fish on Friday, "pasta" on Thursdays and Saturdays, and meat on Sundays. Canned foods, with the exception of tomatoes, are not popular with them. Immigrants from Central Europe bring with them a taste for whole-grain foods such as bread and porridge; they prepare liver, tongue, and other varieties of meat in many ways, and are fond of sausage, cheese, and soup with dried mushrooms. The Czechs spend much time on cooking, and on Sundays have their traditional dishes of rye bread, pork, goose, sauerkraut, beans, pastry, and beer. The Negro as a rule eats much the same food as his white neighbour, which in the rural south usually consists of meat, meal, and molasses, supplemented by greens and fish. The diets of foreign elements, and particularly those of their children, inevitably veer in the direction of the prevailing American taste. All immigrants appreciate the ready availability of white bread and refined sugar, which are often consumed in such amounts as to upset the balance of diets otherwise adequate. The desire for white bread is largely a matter of taste and ease of mastication. Social motives, however, cannot be excluded, since in some parts of Europe the use of black or brown bread is the mark of poverty. It is noteworthy, moreover, that those who cannot readily obtain their own national foodstuffs prefer American foods in their simplest and most pure form. The best way to please a mixed company who have to eat the same meal is, it appears, by plain cooking and the exclusion of mixed dishes of unknown composi-

¹ Published by the National Research Council, National Academy of Sciences, 2101, Constitution Avenue, Washington, D.C. (Single copies available upon request to professional individuals and agencies in the field.)

tion The preference for white bread may be due in part to suspicion, conscious or subconscious of the nature and cleanliness of the constituents used in making a darker loaf. The emergency ration recommended by Miss Charlotte Chatfield for post-war relief in Europe, which consists of a dried soup of skimmed milk, peas, seasoning, and brewer's yeast, a reinforced cereal, a biscuit, and a peanut-soy spread for use with the biscuit, may be objected to because of its unusual and obscure composition, but populations near starvation will be glad of what they can get. The request of a Chinese delegate that, in order to facilitate cooking, soya-bean meal and peanuts should not be mixed together, but sent separately, is more than a hint that the unconventional mixtures composed according to the formulae of dietitians may not always be received with favour.

In addition to studying spontaneous changes in food habits the committee has been interested in the methods by which the population may be induced to change, or preserve, its habits. The merits of propaganda by the Press, radio, cinema, and personal contact have been examined, and the importance of the way of approach, such as the association of good nutrition with good looks in young women, has been emphasized. Obviously the hint has been taken from the modern advertiser. Rhoda Metraux has inquired into the general reaction of the population to food problems. The answers to questions such as "Why is the Government laying so much stress on nutrition?" and "What do you think about the meat shortage?" have been carefully studied. Meat-packing interests have paid special attention to the most effective means of advertising the nutritive virtues of their products, both to the general public and to the medical profession. Apparently in recent years the consumption of meat has tended to decline, and the desire of the meat industry that health should not suffer from this cause may not be remote from their natural desire to maintain home markets. With their abundant supplies of food the U.S.A., in spite of generous help given to their Allies by Lend-Lease, have not yet found it necessary to adopt rationing schemes to cover the wide range of foodstuffs controlled in this country. Problems that have arisen there as a result of the war may appear to us to be relatively trivial. The increased numbers of operatives working on night shifts have led to the usual difficulties of disturbed meal-times. Food arrangements, as well as lack of social contacts, cause trouble in overcrowded Washington. In Detroit many restaurants have had to close down owing to shortage of staff. On the whole, however, it appears that the state of relative plenty in the U.S.A. allows people still to ask the question "What would be nice to eat?" instead of "What can we get to eat?"

Many of the results of the American inquiry are matters of popular knowledge, and often enough epitomized in homely proverbs and nursery rhymes. But if science is "organized common sense" then clearly there are many common-sense observations of human habits that need organizing in the form of systematic collection and analysis. Human ecology is a science in the making, and in this food habits provide an obvious field of study.

SEEING IS BELIEVING

We have recently had the opportunity of seeing four of a series of films on anaesthesia produced by Imperial Chemical Industries. These include one film each on open ether, nitrous oxide-oxygen-ether, intravenous barbiturates, and spinal anaesthesia. They are straightforward teaching films for medical students, and are excellent productions which reflect much credit upon the film technicians and the Department of Anaesthetics of Westminster Hospital who collaborated in making them. The presentation of the subjects, the clear exposition of important principles, the animated diagrams, and the photography are all to be praised. Those with an eye for good lighting and photography will be particularly struck by the quality of some of the close-ups—for example, the cerebrospinal fluid dripping from the lumbar puncture needle. Films of this kind would be a great help to students in the abrupt transition from preclinical to clinical studies. Conventional elementary lectures on anaesthesia might well be replaced by the showing of such films, followed by questions and answers and later by practical demonstrations. One advantage the film has over reality is that, suitably conceived, it can offer the student a rapid survey of the subject as a whole, with emphasis on fundamental principles, thus helping him to see in perspective the detail which he must subsequently master, another, and obvious, advantage is that many students can see the same thing at the same time without having to stand on tiptoe or peer through the chink between the anaesthetist's arm and his body.

The films err in some minor points. In the one on intravenous barbiturate anaesthesia not only are proprietary names used for barbiturates and analeptics which have official designations, but the proprietary packings are shown in close up. The proprietary names, it is true, are familiar—and, it may be pointed out, not of products manufactured by I.C.I.—but the use of registered trade names to describe drugs is undesirable. There has been a welcome tendency in the U.S.A., and more recently in Britain, for manufacturers to be more modest and less confusing with their labels. But in the teaching film the official designations should be used, and none other. Another fault common to two of the films is that the aseptic precautions, as shown, are vitiated by simple technical "howlers". Thus, although it is emphasized that the operator should perform spinal anaesthesia wearing sterile rubber gloves, he is shown putting them on in such a way that there is an evident risk of contamination of the first glove while donning the second. Again, in the painting of the lumbar region with iodine, the swab is repeatedly wiped over the site of puncture after it has touched adjacent areas of skin.

If, as seems probable, films are to play their part in medical education—and, putting the case in its most modest terms, their claims are at least as strong as those of blackboard and chalk—medical schools will have to provide themselves with substandard (16 mm) projectors and sound equipment. At present the lack of suitable films provides little incentive to the purchase of projectors, and the lack of projectors, and hence of a distributing mechanism, is not an encouragement to the production of medical teaching films on an adequate scale. This deadlock will have to be broken by the provision of at least a nuclear library of medical teaching films, and the question will arise: Who is to sponsor such films and with what immediate and remote objects?

The first interest of a commercial film is in its commerce, and it has numerous reputable ways of bringing its name and its goods to the attention of those it wishes to attract.

The production of educational films is one of these ways, and the pharmaceutical industry has, in fact, stolen a march on the official teachers of medicine. The British Council is producing instructional films to show the foreign medical man what British doctors are up to. But British Medicine—if we may indulge in animism for the moment—has done very little for the *British* student in this field. The perilous effect of the "word" on the mind of the student is well described by Dr. Ff. Roberts in an article in this week's *Journal* at page 284. It looks as if the modern student is in danger of clinging to the "text" as faithfully and as slavishly as the medieval doctor stuck to his Galen. We should not let the saying "seeing is believing" become corrupted to "reading is believing." The word may take possession of a man and prevent him from seeing what is in front of his nose. The medical educationist should read Dr. Roberts's article, and have a look at some instructional films.

CONGENITAL ATRESIA OF OESOPHAGUS

The oesophagus is gradually but surely assuming a greater importance in the field of practical surgery, and it is both interesting and encouraging to read the survey of his long experience in injuries and diseases of the oesophagus that Prof. Grey Turner gives in his recent Hume Memorial Lectures.¹ British surgery owes no small debt to Grey Turner for his continued confidence in the future of oesophageal surgery and his insistence that, despite all disappointments, the problems must be resolutely faced. The position of the surgery of carcinoma of the oesophagus was discussed in these columns last year.² As a contrast to this disease, which so often attacks the elderly, there is another, previously hopeless, which occurs at the very beginning of life—congenital atresia of the oesophagus. Grey Turner describes the successful attack which has been made on this condition. The commonest malformation is that in which the upper half of the oesophagus ends blindly and the lower half opens directly into the lower end of the trachea. The clinical features are characteristic. The child may exhibit cyanosis and choking at birth, but thereafter shows the signs of high obstruction in the oesophagus, for it chokes, coughs, and goes blue with every attempt at feeding, as the milk distends the obstructed oesophagus and overflows into the larynx. Because of the fistula between the lower oesophageal segment and the trachea the stomach fills with air and is obviously distended. Death occurs from bronchopneumonia after 4 to 7 days. Gastrostomy is of little avail, because food flows back from the stomach into the air passages. Relief can be obtained only by closing the fistula between the trachea and the oesophagus and restoring continuity of the latter.

Direct treatment is worthy of consideration is shown by the occurrence of this deformity once in about every 2,500 births; in contrast ectopia vesicae is said to occur only once in 50,000 births. There is little doubt that many cases pass unrecognized under a diagnosis of "pneumonia."

Direct attack on congenital atresia of the oesophagus in a newborn child would seem hazardous, but death is inevitable if nothing is done—and the recuperative power of the newborn may be very great. After waiting three years for a suitable case Grey Turner describes how his assistant R. H. Franklin was able in 1941 to close the fistula between oesophagus and trachea and to do a direct end-to-end anastomosis of the oesophagus. Unfortunately the diagnosis had not been made until the third day, by which time the child already had some pneumonia, and death occurred seventeen hours after the operation. This was the first

attempt at restoration in Great Britain, but much earlier work had been done on the problem in America. Cameron Haight and his associates, for instance, have operated on twenty-one patients, in fifteen of whom it was possible to make an anastomosis; and four of these are well and able to swallow normally. These are all lives saved, and it is clear that further attempts are justifiable. If the diagnosis can be made on the first or second day of life and operation performed at once, then there is hope of further successes. Success will, however, come only if the surgeon has studied the pathological anatomy of the deformity, has practised exposure of the oesophagus in the cadaver of stillborn infants, and "from forethought is able to act with precision"—a dictum of Hume's, whose memory is honoured in these lectures.

"JEEP" DISEASE

Under this title the condition known as pilonidal or coccygeal sinus is described in an article by Buie.¹ He quotes a statement of Lane's² that in 1940 in the United States Navy the number of sick days occasioned by pilonidal disease exceeded those occasioned either by hernia or by syphilis. It would appear that this is to some extent due to the fact that even symptomless sacrococcygeal dimples have been excised because it was feared that riding on jeeps and trucks would play havoc with the condition. It is indeed fortunate that the ubiquitous jeep is not the real cause of this disease, for it is a congenital sinus lined by tissue indistinguishable from skin. It usually becomes infected at the age of 20 to 24, and recurrent abscesses are the result, possibly with intervals of freedom for many months. The condition has received little attention from British surgeons. Lockhart Mummery³ drew attention to its congenital origin in 1921. In 1933 R. L. Newell⁴ gave a full description and considered that it was the result of traction on the skin caused by retrogression of the tail bud. There is evidence, however, to show that the condition is just as common in this country as in America. Complete surgical removal appears to offer the only means of a permanent cure. Opinion is divided as to whether primary union should be attempted or the wound should be allowed to granulate. Newell⁴ and Byrne⁵ favour primary union, but the area should be made as aseptic as possible before this is attempted. Abscesses should be incised, and excision be performed only when the wound has become reasonably clean. As there may be as many as five or six minute sinuses in the middle line care should be taken to see that all are removed, otherwise recurrence is inevitable. If this method is adopted healing may take place within two to three weeks, but if the method of allowing the wound to heal by granulation tissue is employed it may be three months before the wound is healed. Only sinuses which are causing symptoms should be excised, for there is insufficient evidence to show that trauma causes them to become infected.

HOURS OF WORK

The correspondence columns of the *Times* have recently published some interesting letters on the perennial problem of "hours of work." They relate especially to the edict of the Ministry of Works, which insisted that the building operatives employed in repairs to houses in the London area should work 65 hours a week for three weeks. As Dr. J. J. Mallon points out in his letter,⁶ the Regional Joint

¹ *Southern med. J.*, 1944, 37, 103.

² *U.S. naval med. Bull.*, 1943, 41, 1284.

³ *Proc. roy. Soc. Med.*, 1929, 22, 1531.

⁴ *Brit. J. Surg.*, 1933, 21, 219.

⁵ *U.S. naval med. Bull.*, 1944, 42, 386.

⁶ *Times*, July 28.

¹ *Newcastle med. J.*, 1944, 22, 1.

² *British Medical Journal*, 1943, 1, 48.

Committee for London expressed the view that the Government is "ill advised to propose such hours," and they suggest "that the maximum hours of work should not exceed 60." He himself considers that even these hours are too many, and tend to lessen rather than increase production and to add to illness, accidents and absenteeism. He is supported in his view by the president of the London Master Builders' Association, who maintains that the leaders of the building industry have consistently stressed that "where hours in excess of 52 per week are worked output is actually less than with shorter hours." He says that his own experience agrees with Dr. Mallon's in proving that men quickly deteriorate under the long hours they have been forced to work during the war. It is only fair to mention the letter of another correspondent, who maintains that there is no need to fear that the men will be overworked by the operation of the 65-hour week, but he gives his case away by emphasizing that the long hours—which include a large number at overtime rates—are fixed in order to "boost" up the pay packets of the operatives. This conclusion was long ago exemplified by the observations made in munition factories, where it was often found that the men preferred the long hours because of the increased pay. Many of them found that by "going slow" they could avoid excessive fatigue and remain in fair health for months and even years. True, their output was diminished rather than increased, but if their employers liked to be so foolish as to pay them for non-existent work, why should they complain?

MEDICAL MYCOLOGY

The Committee on Research in Medical Mycology (Medical Research Council) is interested in a survey of fungous diseases of man, especially systemic mycoses, occurring in Great Britain, both indigenous and imported. To this end it is seeking morbid material for examination and diagnosis from the following sources. (a) Unquestioned cases of mycosis. (b) Suspected cases of mycosis. (c) Possible but unsuspected cases of mycosis. These would include cases of apparent tuberculous disease, found bacteriologically negative, various granulomata, adenopathies, cold or chronic abscesses, etc., for which no microbic cause has been found. Particular attention should be directed to granulomatous lesions in lymphatic glands, lungs, meninges, etc., not proved to be tuberculous, malignant, etc. Specimens from animals, especially rodents, would also be welcomed. Specimens of tissue should be divided in two: one part for cultural, the other for histological, examination. The tissue for cultural examination should be kept free from contamination or antiseptics and placed in a sterilized, air tight screw-capped or bunged tube, in which also a small pledget of sterile damp cotton-wool may be placed only if there is danger of the specimen drying. When much delay in transport and delivery of the specimen is anticipated it may be sent in sterile 50% glycerin. Tissue for histological examination should be placed in a suitable fixative (10% formol-saline will suffice for the majority of specimens). Dry specimens such as hair, skin scales, etc., may be sent in sterilized corked specimen tubes, or folded in sterilized paper. Pus and other fluids should be sent in sterile, bunged or screw-capped bottles or tubes. Slide smears of tissue, exudate, pus, etc., should be sent unfixed. The specimens, with the relevant data, should be sent to Dr. J. T. Duncan, Emergency Public Health Laboratory, Winchester College, Kingsgate Street, Winchester, Hants, who will provide suitable containers if desired, and will return, promptly, containers belonging to other laboratories.

RURAL HOUSING

City slums have at least the advantage of being obvious to those who pass that way. The country slum is just as bad, and may be worse from the point of view of dampness, but it does not force itself upon the eye, and often its lack of hygiene, amenity, or comfort is camouflaged by the picturesque decay of cottage housing. Slums in the country have been largely neglected by housing reformers, perhaps because of the reflection that, after all, the country dweller has the open spaces at his front door to make up for the insanitary conditions within. Improvement in agricultural housing came to a sudden end on the outbreak of war, and many condemned houses have remained in occupation because new houses to replace them have not been built. The policy to be pursued as soon as house building can restart is the subject of a report by a Rural Housing Subcommittee of the Central Housing Advisory Committee,¹ in which various recommendations are made. This subcommittee takes the view that county councils, with some exceptions, have shown little interest in rural housing. Though the tendency of the time is away from the small authority, the subcommittee feels that rural district councils, whose members are aware of local conditions and preferences, should play an important part in housing, while county councils act as guide, philosopher, and friend. It also recommends that in every county there should be set up a joint committee to advise the local bodies on their health and housing functions. A post-war survey of housing conditions in every rural district of England and Wales should be undertaken, and the working-class houses in each district classified according to accommodation, amenities, and state of repair. In rural Wales housing conditions are worse than in rural England. The prolonged and extreme poverty which until lately prevailed in rural Wales has had a disastrous effect on housing, and a special subsidy is recommended for the poorest districts. Another point made is that in many counties of England and Wales the fact needs to be brought home that rural housing is a major health function, and that a sanitary officer should be placed on the staff of every county M.O.H. to advise on rural housing, water supplies, and sewerage. At present there are such officers in only twenty counties. The maximum extension to rural areas of electricity, gas, piped water, and sewage disposal is, of course, to be desired, together with the provision of amenities, such as a village hall, which develop communal life. A few incidental but not unimportant points are stressed. One is the aesthetic aspect of housing in these days of prefabrication and mass production: it is more than ever necessary to make sure that materials and designs for new houses are not unsuited to the landscape. Then it is suggested that the working man's point of view should be sought on the condition and sufficiency of dwellings in a district, and accordingly that housewives should be co-opted on the housing committees of rural district councils. We cannot understand why two members of the main committee should have taken exception to this very sensible point. Finally there is the question of the week-end cottage. If it is shown that people of higher economic level by taking country cottages for week-ends and holidays deprive those who live and work in the country of accommodation they need, then the habit should be discouraged and indeed prevented, but otherwise the subcommittee thinks that this is not a bad thing to happen, and, moreover, many cottage while suitable for occasional use, are not the places chosen for permanent homes and the bringing up of families. The report is issued under the auspices of the Ministry of Health.

"HAVING YOUR LIKENESS TAKEN" OBSERVATION IN THE STUDENT'S TRAINING

BY

FF. ROBERTS, M.D.

According to the Report on Medical Education of the Planning Committee of the Royal College of Physicians the powers of observation of the average medical graduate are "relatively undeveloped." This indictment of a profession which should be essentially naturalistic, terrible as it is, is none the less true. I have known a greatly enlarged spleen missed for over a year. It would seem impossible, while examining the heart, to miss a tumour of the left breast large enough to prevent the patient from lifting the arm, but I have known it happen. These are only two out of the many which I could quote from my own experience. Sir Walter Langdon-Brown tells me of a candidate who could not say whether a woman whom he was examining was married (a material point in the diagnosis), although she was wearing a wedding-ring. An ophthalmologist informs me that he has seen qualified men examining eyes with great care before discovering they were glass. Clinical notes written by many house-officers are so inaccurate as to be quite worthless for immediate use and therefore totally misleading for future reference. It cannot be denied that accurate observation must come first. Without it diagnosis, prognosis, and treatment must all go astray. No amount of theory, scholarship, or specialized knowledge is of the smallest avail if the practice of taking and memorizing observations is not mastered.

The fault, according to the report above mentioned, is to be attributed chiefly to the manner of the student's training. One may go further and wonder whether there may not be something about the system which actually suppresses such powers of observation as the student may initially possess. We must therefore consider in what respects the training is at fault and what remedies can be applied, but before doing so we must inquire whether any factors more general than clinical instruction itself contribute to such a disastrous result.

When Mr. Pickwick entered the Fleet Prison he first had to undergo the ceremony of "sitting for your portrait" or "having your likeness taken."

"The stout turnkey, having been relieved from the lock, sat down and looked at him carelessly from time to time, while a long thin man who had relieved him thrust his hands beneath his coat tails, and, planting himself opposite, took a good long view of him. A third rather surly looking gentleman, who had apparently been disturbed at his tea—for he was disposing of the last remnant of a crust and butter when he came in—stationed himself close to Mr. Pickwick, and, resting his hands on his hips, inspected him narrowly; while two others mixed with the group, and studied his features with most intent and thoughtful faces."

This is no imaginary picture. As his letters prove, Dickens, himself an extremely accurate observer, was describing a scene which he had witnessed through the insolvency of his "Prodigal Father." Living before the days of photography and finger-prints, these ruffians had to rely solely on their eyes and memory. If they failed they lost their jobs—a terrible punishment before the dole was invented. Well might the stout turnkey boast: "We're capital hands at likenesses here. 'em in no time, and always exact." (Italics mine.)

William Beach Thomas describes in *The Way of a Man* how his father's coachman was completely confused by the number 2, "and since his reading and writing at fault, he received his instructions only by word of mouth. There was no need even to repeat them. He was letter perfect, and was not known to forget or mistake any item."

Mr. B. L. Burman, in *Miracle on the Congo*, quotes the following remarkable testimony by Major Glubb, who commanded the Arabs of Transjordan:

"The Arabs have amazing memories. They can report their movements, minute by minute, for 15 days or more, and remember every slightest detail, the colour of a blade of grass, the shape of a particular palm-tree. But the instant they learn how to read and write it's all finished. They forget everything they ever knew."

If, then, the highly developed powers of observation possessed by primitive man are so easily extinguished by the acquisition

of elementary literacy, what chance is there for the survival, let alone the growth, of the rudimentary powers of observation possessed by civilized youth, in the mental costiveness of pre-clinical education? Ward sisters, with minds unclouded by erudition, often put doctors and students to shame by their shrewd observations.

The Three Obstacles

Thus handicapped by their upbringing, students encounter three obstacles in their clinical course: the method of teaching, laboratory methods of diagnosis, and the textbooks. By a grim irony, so far from recognizing these as obstacles they regard them as blessings.

The Method of Teaching

Their undeveloped natural powers of observation lead many students, on entering the wards, to acquire an inferiority complex. The ease and rapidity with which their seniors conduct examinations and make deductions appear to them to be due to some special gift of superior sensitiveness which they themselves can never hope to possess. They fail to realize that what seems to them so marvellous is only the result of interest and practice, and that deductions are only the logical result of observations either made at the time or drawn upon from past experience. Hence when interrogated they so mistrust themselves that they resort to wild guessing and make clumsy attempts to beg the question. Content to accept observational facts from others, they are readily hypnotized by any crankiness on the part of their teachers. A house-physician once told me that a certain patient had a "duodenal ulcer facies." He had been taught, so he solemnly explained, that men with short round faces had gastric ulcers and men with long thin faces duodenal ulcers (or it might have been the other way about). I myself was taught that there was a characteristic facies in diabetes. Unfortunately it is the more conscientious type of student who suffers from self-mistrust. To the man who is sanguine by temperament but without real ability the path is easier. Readily picking up the jargon and bedside manner at their worst, he soon scores a meretricious success which shows him the way to become a "clever doctor." It is self-confidence of the right kind and degree which is so difficult to instil.

Note-taking.—While attention is rightly paid to the writing of clinical notes it is forgotten that here lurks a danger, for notes can be written at the expense of the memory. The sensory impression can be so fleeting and its passage from the sensory areas to the motor cortex so rapid that no imprint is made on the memory at the time. The student has just spent two years in scribbling down anatomical and physiological information which, partly through faulty delivery, he has only imperfectly understood. He has thus mastered automatic writing almost like a medium in a trance, and is well trained to practise this accomplishment at the bedside.

Positive and Negative Observations.—It is always safer to record a positive than a negative observation. I have often read the words "Liver just palpable" when it was obviously not palpable. If the student writes "Just palpable" he can always say, "I thought I could just feel it," but if he writes "Not palpable" he may be thought careless or defective in tactile sense. The result is that notes are full of incorrect and misleading observations. So far from acquiring a habit of accuracy the student develops a kind of protective woolliness. He may never be wrong, but he is never right. He learns not merely to sit on the fence, but to sit on it with both legs on the safer side.

The Bantam's Egg.—A minor factor contributing to the nebulous atmosphere is the traditional practice of using as standards unfamiliar objects such as a goose-quill, millet seed, or bantam's egg. When a friend told me that a certain tumour which he had seen was as big as a bantam's egg, I asked him how big a bantam's egg was. He replied that he had no idea; he had never seen one. Evidently in his student days someone who himself had probably never seen one had taught him to describe a tumour which he was examining as being of that size. He therefore concluded that a bantam's egg was the same size as the tumour. In other words, he was learning not the size of the tumour which was before his eyes but the size

of a bantam's egg which he had little chance of seeing. He was learning not practical medicine but theoretical poultry-farming.

The Clinical Raconteur.—We have all been tortured by this sort of thing. "A few months ago I was called into the country to see a lady. She had a temperature of 101° and a pulse of 120 . . . I decided to operate . . ." Information of this kind is quite devoid of any educational value, for, however instructive the experience may have been to the lecturer, he cannot with the best will in the world make it convey much to his hearers. It is like relating one's dreams enthralling to oneself, but boring to one's friends unless, of course, these happen to be of a Freudian turn of mind.

Laboratory Methods

For a trenchant criticism of the modern reliance on laboratory methods of diagnosis I commend to the reader a recent review in these columns of W. C. Alvarez's *Nervousness Indigestion and Pain*. The following is an extract.

"Recently out of 50 candidates asked the simplest way to distinguish between obstructive and non-obstructive jaundice only three said they would look at the stools, all the others said they would have a van den Bergh test done. A test of doubtful validity as opposed to a simple conclusive observation. Candidates often refuse to diagnose a straightforward case of icteric regurgitation without a Wassermann reaction, and will ask for an electrocardiogram without feeling the pulse. When directed to do so it seems to convey no information to them. One could multiply examples."

One has to be a radiologist to appreciate the full extent of his attitude of mind. Special methods seem to have brought clinical examination to bankruptcy. House-officers refer patients to the x-ray department with the words, "Please x-ray arm," or "Please x-ray spine." The clinical examination of fractures seems to the younger generation completely out of date and unnecessary. "Why bother," I have seriously been asked, "when radiology can do it so much better?" Beyond a doubt laboratory methods contribute materially to atrophy of the senses.

Textbooks

The accompanying Table shows the size of the books which I read when a student and the size of the current editions of the same books.

Book	No. of Pages		Approx. No. of Words plus Word-equivalents in Diagrams	
	1907-12	Current	1907-12	Current
Pre-clinical				
Cunningham's <i>Text Book of Anatomy</i>	1,312	1,514	1,030,000	1,250,000
Cunningham's <i>Practical Anatomy</i>	1,117	1,580	507,000	700,000
Halliburton's <i>Physiology</i>	890	930	390,000	418,000
Starling's <i>Elements of Physiology</i>	707	—	209,000	—
Starling's <i>Principles of Physiology</i>	—	1,205	—	841,000
*Total—Pre-clinical	4,026	5,229	2,186,000	3,209,000
Clinical				
Taylor's <i>Medicine</i>	1,088	1,110	615,000	8,900
Rose and Carless's <i>Surgery</i>	1,315	1,618	709,000	890,000
Eden's <i>Midwifery</i>	690	724	311,000	377,000
Eden's <i>Gynaecology</i>	864	940	437,000	527,000
Green's <i>Pathol.</i>	620	1,136	304,000	575,000
Total—Clinical	4,577	5,528	2,376,000	3,208,000
Grand Total	8,603	10,757	4,562,000	6,417,000

* Allowing for the reading of two physiology books, the usual practice.

To these, of course, must be added those on all the special subjects. In computing the number of words I have made no allowance for diagrams, because these require as much study as letterpress, and the space they occupy is often compensated for by paragraphs in small type. For comparison I may remind readers that the Bible contains about 800,000 words. Some medical authors make Shakespeare (1,100,000) look puny, but perhaps it is hardly fair to judge by quantity.

The Table shows how, with one exception on, these tomes have added to their too too solid flesh with the years, and how in consequence the mental burden increases with each generation of students. Their growth is no doubt partly due to increase in knowledge but chiefly it reflects the expanding

experience of the authors or succession of authors, who forget that the average intellect of successive years of students remains a constant quantity. One may note in particular the rise of nearly 40% in the size of the dissecting manual, one might have imagined that everything worth dissecting had been discovered ages ago. We thought our burden just about as much as we could bear, but our sons have to carry half as much again, one wonders what it will be for our grandchildren and great-grandchildren. It may be objected that students do not have to learn all that is in them. The answer is that they only omit anything at their peril. One glance at the connexions of the sphenopalatine ganglion was sufficient to convince me that they were beyond my power to learn, especially as I had no chance of seeing them properly. I therefore decided, to the astonishment of my more conscientious companions, to ignore them. I reckoned that if the rest of my armour were reasonably secure I could afford to have one chink in it. My weak spot escaped the examiners in anatomy and surgery, but was discovered by the examiners in medicine of all people.

The attachment of students to their textbooks is pathetic, and well it may be, for are the books not their bulwarks against defeat, their sure shields against their implacable enemies the examiners? I have often wondered why students, chiefly women, carry their large *Cunningham's* or *Gray's* with them to anatomy lectures. Are they so afraid of being without them even when they should least require them? Our mental outlook, in fact, shows little if any advance from our mediaeval ancestors' apotheosis of Galen, despite (or perhaps because of) the blessings of modern scientific education.

The following typical incident well illustrates the prevailing subservience to the textbooks. A young practitioner referred a patient to me with what he had labelled a dinner-fork deformity. But the wrist showed not the smallest resemblance to a dinner fork. The forearm was perfectly straight over its whole length, but there was a slight swelling over the carpus due to a fractured scaphoid. Here was a case of perverted observation. The young man had evidently argued thus: "This is probably a Colles's fracture. In the pictures I have seen in the books this causes a dinner fork deformity. Therefore what I see before me is a dinner fork deformity." How otherwise could an intelligent man—for intelligent he certainly was—make such a mistake? He could no doubt have written an admirable description of Colles's fracture, but he had not been taught to look. His mind, being completely captive to the books, found no difficulty in interpreting his sensory impressions in a form acceptable to them. The books have become the mirrors in which students see patients, and all the laws in the reflecting surface distort the mental image.

These unwieldy tomes should be used solely for reference. When students plough through them they merely subject themselves to mental torture. Their memory and concentration are strained in the wrong place. No one will deny that the amount of concentration involved in attendance at clinics is only a fraction of that which is demanded of a boy in a classical sexton form or of a person learning to play in a symphony orchestra. After a day spent, if not languidly, at least with nothing to prevent his mind from wandering, the medical student goes home to burn the midnight oil. He opens one of his tomes at page 873 and makes a fierce resolve to read 20 or 30 pages, and he goes to bed wondering how much he will remember. He reserves his brain during the day for the wrestling which must be his at night, he tries to learn from the books what he should have learnt from life. A person who wants to learn bird-watching goes and watches birds with the help of an expert, he does not begin by buying a 1,200-page book on the subject. And yet medicine is or should be just as naturalistic as ornithology. Small wonder that the College of Physicians finds the student lacking in curiosity and initiative. His training, in fact, makes him the reverse of quixotic, for whereas the Don's imagination was so heated by romantic literature that the commonplace seemed exciting, the student's brain at a slightly lower level of cerebration is so chilled by factual knowledge that the exciting seems commonplace.

The Remedies

The situation calls for nothing short of a revolution in the method of teaching. The system must be imbued with the

commando spirit. A student will not observe unless he is interested, and the only way to make him interested in a subject which he finds difficult is to make him interested in the growth of his own faculties. Interest and observation reinforce each other, and only by their combined development can self-confidence of the right kind be acquired. At the outset, therefore, he should be put through a rigorous discipline in observing accurately and in giving an account of his observations without the aid of notes. I am told that some such system is used for naval cadets. It would be necessary to work out a graduated system of exercises in observation on a psychological basis, and this would be one of the functions of the staff college which I have recently advocated in these columns. The problem should be studied from every point of view. It is probable, for instance, that medical men have much to learn about the study of the human features from portrait-painters. A great deal, too, might be done in regard to the combination of sensory impressions. I suggest that rubber models might be made of the commoner uterine diseases, and the student taught to palpate them with his eyes fixed on diagrams and post-mortem specimens of the same conditions. Tactile and visual sensations would thus reach the brain together and, combined, would produce a far more lasting impression than if they arrived at different times.

The emphasis being laid on observation, the student would learn to see laboratory methods in their proper perspective, as aids to bedside diagnosis; and whenever a laboratory test disproved a clinical observation which he had made he should not rest until he had discovered whether, and if so how, his senses had led him astray. The time spent at clinics should be a continuous mental discipline calling forth all his powers of attention and concentration. By tea-time he should be pleasantly fatigued by the mental effort (not merely by holding a retractor while his chief removed appendices, as was my fate), and he should be incapable of absorbing any more information for the rest of the day. Apart from reasonable recreation—and Heaven knows he gets little enough—he should spend his evenings in broadening his mind by general literature, nature, or art, and by taking an active part in some form of social service, an avocation which would teach him far more than the lectures on social medicine with which the College of Physicians is so anxious to burden him.

As for the great textbooks, their proper place is the hospital library, where the student should use them only for reference. When some special point puzzled or interested him he should be given every encouragement to worry it out by delving as deeply into the literature as he liked; but for ordinary purposes small handbooks are all that he needs, and these he should know thoroughly. It is the superficial reading of the great books which is so harmful to mind, body, and spirit, and the only way to stop the practice is by so ordering the examinations that learning acquired in this way is unprofitable. Clinical teachers might do worse than model themselves on Agassiz, the great biologist of Harvard University, who would send a student back time and time again to the object he was studying until his description was accurate. Agassiz wanted students, not textbooks. "The book of nature," he used to say, "is always open. Strive to interpret what really exists. If you study Nature in books you cannot find her."

The student should not acquire the large books until the day when he is qualified. On that occasion I would have them presented to him with some such words as these: "You have studied for yourself all the commoner diseases. In these books you will find more about them and about the rarer diseases which you have not seen. Remember that although they are the fruits of great experience, their authors are men of flesh and blood like yourself, capable of error and capable of accepting and perpetuating the errors of others. Be prepared, therefore, to believe that the books may be wrong and your own observations right." If this practice were adopted the student might capture at least some fraction of the thrill which Keats felt "on First Looking into Chapman's Homer," and we should not have so many doctors too inhibited to read books when they can really profit from them by the memory of weary nights spent in reading them for examination purposes.

It may be objected that the changes I advocate are too revolutionary. To this there are two answers: first, the com-

plete failure of the present system is admitted by those more authority than I can command. If the College of Physicians admits it we may be sure that the change is justified. Secondly, we are living in a revolution, and proposals are no more radical than the transformation which has taken place in military training under the force of circumstances. The teaching of medicine has, under the influence of tradition, too long remained static, and must now partake of the dynamism which we see infecting all around us.

"But," it may be said, "you are just as bad as all other would-be reformers. You too want to add something to the syllabus—a course in observation." To this I reply that, so far from being an addition, it would be a subtraction. If every student were taught at the outset to be a self-reliant and reliable observer, if his likenesses were, in the words of the stout turnkey, always exact, and if he were to put more trust in his senses and less in his books, there could not in the long run be an enormous economy in time. Furthermore we should breed a type of doctor not jaded by the memory of second-hand information, but fresh in spirit and outlook from reliance on first-hand observation. We must resuscitate medical education to its rightful state—a naturalistic study.

Conclusion

I will close, as I began, with Mr. Pickwick, who surely spoke the last word on the ideal medical student. Before he was disillusioned by Mr. Benjamin Allen, of "rather a mild appearance," and Mr. Bob Sawyer, "something like a dissipated Robinson Crusoe" (neither of them typical of their class, period, let us hope), that incorrigible optimist, "casting nightcap energetically on the counterpane," uttered a memorable pronouncement: "*They are fine fellows, very fellows; with judgments matured by observation and reflection, and tastes refined by reading and study. I am very glad of*"

Yes, and it is the duty of the medical schools to give it fine fellows every chance to reach this ideal.

MANUFACTURE OF PENICILLIN

Regulations have now been issued governing the manufacture of penicillin and will form the seventh schedule to the Therapeutic Substances Act. From now on any person manufacturing a penicillin preparation for sale must obtain a licence and comply with prescribed conditions as to strength, quality and purity. Application for licences should be sent to the Ministry of Health, London, S.W.1, the Department of Health for Scotland, Edinburgh, or the Ministry of Home Affairs, Belfast. The Regulations are given in full below.

Definitions and Proper Names

1.—(1) Penicillin (crude filtrate) is the solution obtained by filtration of cultures containing penicillin grown on or in a liquid medium, or of extracts from such cultures. Its proper name is "penicillin (crude filtrate)."

(2) Penicillin (dried crude filtrate) is the substance obtained by reducing penicillin (crude filtrate) to a dry condition. Its proper name is "penicillin (dried crude filtrate)."

(3) A penicillin salt is the substance separated by the application of chemical and physical processes from the culture medium in which a mould producing penicillin has been grown, and reduced to a dry condition. Its proper name is "penicillin" followed by the word or words indicating the nature of the preparation, as, for example, "penicillin (sodium salt)."

(4) In this schedule "penicillin" means the anti-infective organic acid which is known to be produced by *Penicillium notatum*; "preparation of penicillin" means penicillin (crude filtrate), penicillin (dried crude filtrate), or a penicillin salt or solution thereof.

Standard Preparation and Unit of Standardization

2. The standard preparation is a quantity of a dry penicillin kept at the National Institute for Medical Research, Hampstead, London.

3. The unit of penicillin for the purpose of these regulations is the activity contained in such an amount of the standard preparation as may be indicated from time to time by the Medical Research Council.

Tests for Potency

4. Preparations of penicillin shall be tested for potency in units which shall be determined, by comparative tests in relation to the standard preparation, by a method approved by the licence-

authority. The potency so determined shall be expressed in units per c cm. in the case of liquid preparations and in units per mg. in the case of solid preparations.

Quality

5—(1) Penicillin (crude filtrate) containing less than 10 units per c cm., and penicillin (dried crude filtrate) containing less than 0.75 unit per mg., shall not be issued.

(2) A preparation of penicillin intended for use in making solutions for parenteral injection shall contain not less than 150 units of penicillin per mg.

Tests for Sterility

6—(1) The provisions of Articles 16 to 20 of these regulations relating to the application of tests for sterility shall apply to preparations of penicillin with such modifications, if any, as the licensing authority may from time to time approve.

(2) The provisions of Part I (C) of the Second Schedule to these regulations shall apply to a preparation of penicillin which is alleged to contain *Penicillium notatum* or any other organism in living condition.

Tests for Freedom from Abnormal Toxicity

7. Preparations of penicillin intended for use by parenteral injection shall be subjected to the following test for absence of abnormal toxicity.

A quantity of the preparation containing not less than 1,000 units of penicillin, in a volume not exceeding 0.5 c cm. of a watery solution, shall be injected intravenously into each of five normal mice each weighing approximately 20 g. The sample shall be treated as having passed the test if either—(a) the injection does not cause death in any of the mice within twenty-four hours from the injection; or (b) the injection having caused death in one only of the mice within that period, further such injections in five other such mice do not cause the death of any of those mice within twenty-four hours from the injection.

Tests for Freedom from Pyrogenic Substances

8. Preparations of penicillin intended for use by parenteral injection shall be subjected to the following test for absence of pyrogenic substances.

A quantity of the preparation containing not less than 10,000 units of penicillin, in a pyrogen-free watery solution, shall be injected intravenously into each of three normal healthy rabbits each weighing not more than 2.5 kg. The body temperature of the rabbits shall be recorded one and one-half hours before the injection and either continuously for three hours after the injection or at the end of one, two, and three hours after the injection. The sample shall be treated as having passed the test if the average maximum temperature increase of the three rabbits does not exceed 1.2° C.

Container and Labelling

9. The container for liquid preparations of penicillin shall be made of glass as respects which the licensee has satisfied himself that it does not lead to the destruction of penicillin.

10—(1) The label on the container shall indicate whether the preparation is suitable for parenteral injection.

(2) In the case of preparations of penicillin intended only for local application, the label on the container and the label or wrapper on the package shall bear the words "Not to be injected" clearly printed in a distinctive colour.

(3) If a preparation of penicillin as issued for sale is combined with any substance other than a simple diluent, the exact nature and strength of that substance shall be stated on the label on the container.

AN L.C.C. RHEUMATISM UNIT

A report on the rheumatism unit at St. Stephen's Hospital, Fulham Road, was given at a recent meeting of the London County Council. The clinic was instituted twelve years ago for the purpose of providing beds for patients from the British Red Cross Society's clinic for rheumatism, where no facilities for in-patients existed. Out-patient clinics for patients referred from other council hospitals were started, and in 1943 the number of out-patients was 1,784. In the course of this work it has become obvious that the usual in-patient and out-patient facilities are inadequate for the proper care of these patients, and that the sociological aspect needs to be taken into account. A special almoner has accordingly been appointed to visit the homes and workplaces of the patients, unravel their domestic and emotional problems, and make arrangements where necessary for treatment at a spa or convalescent home. An occupational therapist attends at the hospital for diversional and remedial work, and various kinds of general treatment are

afforded. Treatment of the local manifestations by orthopaedic and physiotherapeutic measures and by rehabilitation in the widest sense of the word is also carried out. Research studies have been undertaken at the unit. Postgraduate teaching takes place under the auspices of the Fellowship of Medicine Post-Graduate Association. The unit is doing its work under difficulties many or most of which are inevitable under war conditions.

Reports of Societies

A MIXED PÁTH. BAG

A general meeting of the European Association of Clinical Pathologists was held at the School of Pathology, Oxford, on June 24. The president, Dr. S. C. DYKE, in taking the chair, pointed out that the meeting was being held in spite of restriction on travel because many members anticipated that they would shortly be returning to resume work in their homelands.

Prof. S. JELLINEK (Vienna), describing the peculiar character of injuries by lightning, said that they caused neither pain nor reaction of the tissue, they could not be classified as burns nor should they be treated as such. He demonstrated numerous photomicrographs of the affected tissue showing screw-like deformities and transformations in a typical geometrical pattern, not applicable by traditional histopathology and intelligible only in the light of Faraday's basic laws on the lines of electric force (phenomenon of polarity).

Dr. K. S. ROSENBERG (Prague) reviewed recent work on the prognostic value of estimating sugar in pleural effusions. In 115 cases of tuberculous effusions he could find no connexion between the sugar level and findings of tubercle bacilli, red blood cells, blood-sugar levels, and the prognosis of the case. Bacterial action did not influence the sugar level. The average sugar level was between 5 and 20 mg per 100 c cm. He suggested that the enzymes of polymorphs might lower the sugar. Three cases of carcinomatous effusions with sugar values of over 110 mg per 100 c cm. were reviewed. The possibility of diagnostic value in these cases was suggested.

Drs. ELIZABETH DELIKAT (Bratislava), S. C. DYKE (Oxon), and Mr. CYRIL L. BUTLER demonstrated findings on a case of hyperproteinaemia and asked for a diagnosis: male aged 46 had suffered from persistent epistaxis, papilloedema, and retinal haemorrhages, and enlargement of the liver and lymph glands. Total serum protein 10 g per 100 c cm, globulin 7 g, albumin 3 g. There was anaemia but no abnormal cells. Histological appearance of the excised lymph node suggested lymphatic leucos. After blood transfusion the epistaxis ceased and the hepatic and glandular enlargement disappeared. During the next four months the patient appeared well, except for a slight degree of anaemia, persistent papilloedema, and hyperproteinaemia, lately, Bence-Jones proteinuria. Bone marrow by sternal puncture was normal. The general opinion of the meeting was that this would eventually prove to be a case of lymphatic leukaemia.

Dr. I. FRIEDMAN (Prague) made further observations on the growth of *M. tuberculosis* in a fluid medium containing embryonic tissue. Penicillin reduced the danger of contamination. Primary cultures from sputa grew in some cases after 3 to 5 days, usually at the end of the first week. He showed photomicrographs of the morphological features of colonies: Medusa-head-like colonies of the human type; serpiginous colonies with a tendency to a more compact growth of the bovine type; widely scattered colonies or loose groups in or round the macrophages in the avian type.

Dr. J. LUGAR (Prague) discussed the importance of penicillinase for diagnostic purposes in cases treated with penicillin, where it was essential to inactivate penicillin in blood or exudates. Penicillinase was produced by a strain of *B. subtilis* grown in digest broth aerobically at 37° C. for two to three days, and filtered. Sterile filtrate remained stable for at least 6 to 8 weeks in the cold. The potency of penicillinase depended on the conditions of growth: under optimal conditions 1 c cm. of the culture fluid would inactivate 4,000 to 6,000 units/c cm. of penicillin over 24 hours.

Dr. F. PICK (Prague) demonstrated a case of a primitive nervous-tissue tumour more akin to neuroblastoma than to Wilms tumour, growing from the left adrenal. The patient, a boy aged 6, suffered from hyperkeratosis since birth, asthenia, and anaemia. Intermittent haematuria for 5 months. Enlargement of abdomen noticed 6 weeks before death. Tumour weighed 4 lb. 6 oz.; size 8 in. \times 4 in. \times 5 in.; metastases in liver; no metastases in skull or elsewhere. The characteristic histological findings of a neuroblastoma and Wilms tumour were present.

Dr. E. DELIKAT demonstrated an aberrant thyroid removed from the right side of the neck of a man aged 20, originally diagnosed as tuberculous adenitis; also a polyp of the stomach from a patient suffering from macrocytic anaemia with achlorhydria—irresponsive to liver. The removal of the polyp did not alter the course or nature of the anaemia.

Nova et Vetera

APPRENTICE BOOKS AT BARBERS-SURGEONS' HALL

The apprentice books at Barbers' Hall date from the year 1657. It is, however, possible to recover the names of a very large number of apprentices of an earlier date than this, as well as the names of their masters, from the *Wardens' Great Accompt Book*, a huge folio which dates from 1603. The master was bound to present his apprentice and pay the sum of 2s. 6d. to the company, and these records of half-crown payments will be found there. When I had permission from the company to transcribe the records of apprentices I copied every entry from 1603 to 1745. These copies were presented to the Royal College of Surgeons under the terms of permit given me by the Barbers' Company.

Literally thousands of names have been recovered from this source, and when they have been arranged in alphabetical order and annotated they will be of the greatest value for a fuller biography of the surgical profession in this country than has yet been possible. One would like to see some such a series compiled for the surgeons as Munk did for the Royal College of Physicians, and I am not without hopes that this may be accomplished at some future date.

The records in the apprentice books during most of the period are in Latin and give the name, home town, and occupation of the father and the period of time (usually seven years) for which the apprenticeship was to run, as well as the name and occupation of the master to whom the apprentice was bound. The premium paid to the master is not noted in the earlier volumes, but in the eighteenth century it is almost always recorded. In 1719, for instance, the Rev. Wm. Scrafton paid £262 10s. to Samuel Palmer, surgeon, for his son Richard Scrafton for the term of seven years. Richard was afterwards on the staff of St. Bartholomew's Hospital. Less-known surgeons accepted smaller premiums, and in the case of a barber the premium was often as low as £20, and sometimes even less.

One of the first things that struck me in copying these records was the large number of masters whose occupation was not that of a barber-surgeon. Yet all of them must have been free of the company, probably by patrimony. The clerks who kept the books wrote good legible hands, but their spelling of place names seems often to have been on the phonetic principle. For example, Randolph Church, tanner, of Draden, co. Salop, apprenticed his son, Randolph, to James Wheeler, surgeon, for seven years in 1701. The younger Church was baptized at Market Drayton, in Shropshire, August 30, 1683. This apprentice was also later a member of the staff of St. Bartholomew's Hospital.

It was often a bit of a puzzle to settle the correct translation of Latin word used for the parent's occupation. "Agricola" would seem to denote a farmer, but I expect that "yeoman" would be better. The word "lanius" gave me a good deal of trouble. I could not find it in any of the small glossaries of mediaeval Latin at my command. In the end I did what anyone else would have done at the beginning, and found it in Smith's Dictionary as classical Latin for a butcher. Some odd occupations figure at times on these records; I came across at least one example of a longbow-string maker, and occasionally the clerk would air his knowledge of classical words, as when he rendered a harness-maker "Ephippiarius."

If the master happened to die before the apprentice was out of his indentures the boy was "turned over" to another master, and in later examples a proportion of the premium was also "turned over" to the new master. Some of these youths were "turned over" more than once. The age of the apprentice is not stated, but as a general rule it was from 14 to 16 years. Church, it will be seen, was about 18 years old when he was bound. Very few of these boys had the advantage of a university career before taking up surgery. I came across one case in which it was probable that the son of a Leicester-

shire parson had been at Cambridge before coming to Barber Hall. Perhaps he had been sent down. It is unfortunate that the apprentice books do not start at an earlier date than 1657. We miss the details of Richard Wiseman's parentage. His apprenticeship to Richard Smith, surgeon, in 1636-7 is obtained from the *Great Accompt Book*.

To show that one cannot always trust the spelling of the clerks who kept the books it is only necessary to state that John Knight, who later became Serjeant-Surgeon to Charles II, is entered in the *Accompt Book* as the apprentice of Laurence Roe. It should have been Laurence Loc, who was at one time surgeon to St. Thomas' Hospital. And I think it is not unlikely that the Thomas Blathwait whom Peachey was unable to identify is the individual whom the clerk entered as Thomas Brathwait, who was apprenticed to Latimer Ridley, surgeon, in 1712 at a premium of £50. He was "turned over" to William Dickinson, surgeon, in 1714, and again to Richard Lee, surgeon, in 1719. In the last instance his name is spelled Braithwaite. He took up his freedom in the last-named year.

Never again, I fear, will the surgical record searcher work under such pleasant conditions as I did in the old court room at Barbers' Hall.

R. R. J.

CENTENARY OF A MEDICAL SOCIETY

In the State of Pennsylvania the Lancaster City and County Medical Society has celebrated the hundredth anniversary of its foundation. The occasion was marked by a public meeting attended by many representatives of medical organizations in Pennsylvania and other States, and a letter was read from the President of the U.S.A., who in his message of greeting noted the great contributions made by the medical profession of Pennsylvania to the life of the nation. A note on the history of the centenary society has appeared in the *Journal of the American Medical Association* of May 27. The Lancaster County Medical Society, it says, was one of the first to encourage the entrance of women into the practice of medicine, and it mentions the names of some notable physicians who have been members. A commemorative number of the Society's *Bulletin* includes facsimiles of the early notices associated with the foundation in 1844 and two accounts of the history of medicine in Lancaster.

A presentation was made to Mr. W. Spencer Howells on his retirement from the presidency of the Pharmaceutical Society of Great Britain; when his successor, Mr. F. G. Wells, handed to him a replica of the badge worn by Mr. Howells during his term of office. The original gold badge, valued at £200, worn by presidents of the Society since the days of William Allen, F.R.S., who first held office in 1841, was stolen by a burglar when Mr. Thomas Marns was president in 1937, and the present replica of it is the only one in existence. The new badge was designed by Mr. Omar Ramsden.

Correspondence

Military Psychiatry

SIR,—I am indebted to Dr. B. H. Shaw for drawing attention in his letter (Aug. 12, p. 222) to the apparent discrepancy between psychiatric precept and practice contained in the article "Two Years of Military Psychiatry in the Middle East" (July 22, p. 105). Dr. Shaw suggests, in view of the statement made in the article in question—e.g., that so many of the patients admitted to psychiatric centres and hospitals showed evidence of markedly abnormal personalities prior to their breakdown and that psychiatric casualties are potentially "infective" and constitute a potential menace to the morale of the group as a whole—that it was illogical to return such a high percentage of neurotics and psychotics to duty. He states that the vast majority of these men were in reality most unstable "misfits" and should in consequence have been "eliminated." If the final decision concerning return to duty could have rested entirely on theoretical grounds, few of us would disagree with Dr. Shaw that it would have been preferable for many of these men to have been evacuated from the Middle East and returned to the United Kingdom. The decision upon disposal, however, had to be made with regard to wider issues and against the background of the military situation as a whole. During the period under review the manpower shortage was serious, operational requirements and commitments were heavy, and as a result of the closing of the Mediterranean and of operations in widely scattered and remote

parts of the world the shipping situation rendered it imperative that evacuation of cases should be reduced to a minimum. It was only after careful consideration of these and of other factors—*vs.*, for example, the undesirable effects on morale of evacuating psychiatric cases on a large scale—that the policy of retaining as many cases as possible in the command on at least some form of duty was adopted.

It is, of course, necessary that the statement "returned to duty" should be viewed in its proper perspective, only a relatively small proportion of men in any expeditionary force, even of those on full duty, are actually engaged in a battle area. It may also not be altogether irrelevant to mention the effects of treatment. No extravagant claims are put forward for the results of treatment in chronic constitutional neurotics and psychopaths, but it is reasonable to believe that treatment helped, if not to cure, at least to allow of their return to duty (selected or modified duty if necessary) without undue risks either to themselves or to others. No illusions were entertained that these soldiers might not break down again and they were certainly not discharged to duty in any spirit of easy or undue optimism, but the results in practice sufficiently justified the policy adopted and the actual relapse rate was inconsiderable. That so many of the neurotics and psychotics discharged to duty did in fact make good progress and show a successful readaptation to their duties was due in no small measure to the interest and supervision exercised over them by their unit medical officers and tribute may here be fittingly paid to the invaluable co-operation and sympathy shown by regimental medical officers throughout the Command in the after care of these patients—I am, etc.,

H B CRAIGIE
Lieut-Col R A M C

A National Pathological Service

SIR—We have read with interest the purely destructive criticism of Drs Heaney, Turner, and Haler in your issue of July 15 (p. 95). As pathologists in charge of laboratories, but not directors under the new plan, we should like to emphasize that we consider some such scheme essential for the progress of good hospital and public health laboratory work, and that we have no misgivings about its central co-ordination provided it is our own senior colleagues who do the co-ordinating, as is the case at present in the Emergency Pathological Service and the Emergency Public Health Laboratory Service.

Through their efforts since 1939 a much closer relationship than ever before has existed between laboratories serving teaching hospitals and pathologists working in smaller departments providing a co-ordinated service of routine consultative advice such as is beyond the scope of existing bodies like the Association of Clinical Pathologists and the Pathological Society. We feel that it would be lamentable if in the future we should slip back into the relatively isolated units which existed before the war. It is clear, however, as was pointed out in the letter of June 10 (p. 790), that regional administration should be carried out by senior pathologists with a wide experience of diagnostic laboratory work, the university professors of bacteriology, chemical pathology, and morbid anatomy acting only as advisers in their respective specialties.

We would welcome a scheme in which pathologists can temporarily move from one unit to another, as it is only by daily contact with another pathologist's laboratory that one can appreciate the advantages that his method may have over one's own. We would also point out that if such movements, especially in the case of senior pathologists within a co-ordinated service, were in the main, of a voluntary character they would not then feel that their security was in question. Finally, we consider that coroner's post-mortems should be carried out by the hospital pathologist in the area and not by general practitioners but such pathologists should have had adequate experience and training in morbid anatomy and medico-legal work. Where a pathologist is carrying out coroner's work for a large area it will often be preferable for him to be wholly employed on this work, in which case he should have the status equivalent to other senior pathologists in the service, and have full access to a morbid histology department in his area. We would point out, however, that a formal approach on this

subject to the Coroners' Society before an efficient and well-coordinated service is available in all areas might well be considered premature—We are, etc.,

H B MAY	F E CAMPS
C J C BRITTON	J R GILMOUR
J S FAULDS	D STONE
F C O VALENTINE	C F BARWELL

Service Medicine

SIR—I have just read the letter by J A Valentine (April 1, p. 470). I know the time lag of this reply will be great, but I would ask your indulgence to publish this reply from a regular R A M C officer, even though he may be young as regards service.

First may I join issue with J A Valentine when he states that the letter "so accurately" expresses the views of many serving members of our profession. This statement, of course, is utterly and completely false. Now may I pass to the extracts themselves. I have the greatest respect for the 'civil' front, but surely the burdens that were borne by the troops in the Western Desert from the days of Graziani's advance to Sidi Barrani until the victorious advance of the Eighth Army were extremely heavy as regards 'feeding, comfort, transport, and relaxation (especially alcohol)', but perhaps your correspondent never spent a 'hot weather' in the desert, or, perhaps, too, he has not spoken to anyone who was in Tobruk fortress during the siege, and got their views on "relaxation (especially alcohol)". He cannot obviously realize what a shortage of doctors there was in the early days in the desert, and what a nightmare that must have been to higher authority. The complacent talk of "over staffing" merely shows ignorance of military requirements: hospitals have frequently to replace casualties in medical units in the field, supply R M O's temporarily, and, too, of course, at any moment they may have to move to an active theatre of operations, where a full staff is a necessity. For my part, during a long stay in the Middle East I do not think I have once come across a hospital that was fully up to strength all the time in either medical officers or nursing orderlies.

Your correspondents' talk of not having enough work to do merely shows a lazy and indifferent attitude to his job and, too, an ignorance which is nothing short of appalling. Surely he has read the medical statistics of the North African campaign, and, in fact, of any campaign the British Army has taken part in. If so, even he must realize the importance of preventive medicine, inasmuch as casualties from sickness always outnumber, and that by an appreciable margin, the battle casualties. What did this man do with his spare time? one wonders. Is he so knowledgeable that he did not need to spend any time on camp hygiene inspections? Do strenuous antisy measures to combat dysentery mean nothing to him? Does he know all about antimalaria measures, and, if so, is he sure that his troops do—to mention only two of the decimating diseases of wartime? Did he ever lecture his men on VD—another wartime problem? Did he ever inspect the men's food and how it was cooked, where it came from, and what condition it came in, and was there sufficient variety, and did he ever visit the men's canteens to see how they spent their off duty time? Did he ever discuss their problems with them—both problems in their unit and maybe their homes? But one could go on *ad infinitum* in this strain. No, your correspondent condemns himself out of his own mouth. Your good medical officer has always plenty of work to do. Your bad medical officer merely grouches about lack of work when it is all round him. Or 'bad staffing' I can only say it is hard to believe that a C O and, too, an A D M S are not equally able to judge as regards the staff under them, and are able to adjust matters to their satisfaction, which, of course, would not probably suit your correspondent. As to equipment, I think it is excellent. There were difficulties in the days of the long sea route to the Middle East, and a lag in supply of all arms—not only medical equipment—was inevitable, but when the materials were available we got the very best. Many of us learnt to improvise—a word apparently foreign to your correspondent.

In conclusion I should like to say that I think a slur is cast on the profession as a whole by your correspondent's ill-timed

remarks that importance is put "first on paper-work, next on the staff, and last of all on the patient." Surely a doctor is a doctor whether in uniform or not. I myself have seen, and so must the great majority of your readers, surgeons and physicians toil for hours on end to save a man's life—in fact many men's lives—when everything seemed hopeless, and those men have recovered. Then, and only then, was the paper-work considered. The advances of medicine and surgery have been great in this war, but always there are the ability and the zeal of the individual doctor necessary to bring those advantages to the patient who requires them. Fortunately there are always the men to do this. My only advice to your correspondent is to go to his C.O. and request that he be allowed to go "back home again and be ensconced in the worries of civil practice." We do not need men like that in the Services.—I am, etc.,

S. F. CRANSTON,
Major, R.A.M.C.

SIR,—I have read with great interest the many letters which have appeared recently on the subject of Service medicine. May I be permitted to give some of my own views on the subject which may be of general interest. The letters which have appeared so far can be divided into two main classes. There are those strongly in favour, which have come from high-ranking consultants, and those strongly against Service medicine, which come from the more junior medical officers. Unlike the writers so far, I propose to steer a middle course. It is obvious that there are two sides to every question, and while the R.A.F. Medical Services are very good and well equipped, there are many points that jar my still civilian brain. These jarring points, however, are common to all Services, whether medical or not.

There are two main reasons why a military medical service can be so advantageous from the patient's point of view. First, there is general keenness on the part of the unit medical officer, and, secondly, there is the element of compulsion. A keen unit medical officer can do a great deal to improve conditions and morale in a camp. A sanitary inspection should be more than just a latrine tour; it should signify that the medical officer is out to see that everything is being done to keep hygienic conditions up to scratch, with dire penalties for those who fail to do their bit. The unit medical officer should treat his Service patients as if they were his private patients. The other main factor in maintaining positive health is compulsion; if an airman is ordered treatment he must report for it as instructed or disciplinary action may be taken against him. That, in my opinion, is where the medical services of the Forces score over doctors in civil practice.

It appears to me that one of the main reasons why there is such a dislike of Service medicine among the more junior medical officers—apart from those who would probably have joined the Forces in any case had there been no war—is this element of compulsion. One may dislike to have to do this or that, contrary to one's general beliefs, as instructed in a policy letter from higher authority, but it is not for the unit medical officer to lay down policy; his sole job is to maintain the health of his unit, carry out policy, and obey orders.

It has been said that there are too many forms to fill in, but this is not confined to Service medicine: civilian practitioners, too, have their forms. But may I say this in support of most of the forms that I have come across: they usually give the maximum of information in the minimum of space, and accurately completed medical history and case sheets can be of great value. The only drawback about these is that they do not always arrive simultaneously with their owner in a unit.

Medical equipment and stores are extremely good, and we have nothing to grumble about there; the only snag is the "accounting" of them—a type of higher mathematics which rifies me. But no doubt this is necessary considering the vast amounts of medical stores and numbers of units to be supplied.

Although anxious to return to the relative freedom of civilian life at the end of the war, I still think we should take the rough with the smooth. We cannot all have the jobs that we, or our relatives for that matter, would like most, nor can we all gain glory and medals on the battlefield. There are

many "stooge" jobs in the Services, and it is up to us to them as best we can. We should remember that we are our own masters, but servants of the State, and it is up to us to keep the medical services running smoothly, no matter how we are or how hard it may be for the individual. No one can penalize us for trying our best, and no one in higher authority can expect more of us.—I am, etc.,

C. M. CHAMBERS,
Fl. Lieut., R.A.F. Medical Service

Infant Feeding

SIR,—I was interested to read Dr. P. Boucher's letter (July, p. 160) on some common errors in infant feeding. I agree entirely with his remarks concerning the instructions printed on the labels of dried-milk preparations. I would go further and say that I find it difficult to understand how any infant can be expected to thrive if such directions are rigidly followed.

The boggy of over-feeding is, I consider, even more important. It would appear that at many welfare centres a weekly gain over 7 or 8 oz. is looked upon as a sign of over-feeding, notwithstanding that the infant may be perfectly contented and show no abnormal signs. Many infants in the early weeks of life will gain up to 12 oz. a week or more, and it is usually a small baby that does this and is in need of it. Many infants are made miserable and wretched because the mother has been instructed to reduce the breast-feeding time or decrease the amount of bottle-feed. The effect of this on the nursing mother is that she rapidly loses her milk, because her child is fretful. A vicious circle is set up, and there begins a desperate search after this or that proprietary food. The same end-result is brought about when the mother is first given her instructions with regard to breast- or bottle-feeding if these instructions are too rigid and make no allowance for individual variation.

Ordinarily I see about fifty infants a week, and over the past ten years I cannot remember seeing an infant that had suffered from "over-feeding." No one would think of controlling the weight gain of the young adolescent. Why interfere with the infant's natural appetite?

Dr. Boucher's plea for a common-sense attitude toward infant feeding is a timely one. To this I would add a plea for greater elasticity with regard to instructions to mothers. This may mean more time and trouble to begin with, but will be amply rewarded by a happy and contented infant.—I am, etc.

London, S.W.20.

N. KRAMER.

Prevention of Industrial Dermatitis

SIR,—Dr. Howard Mummery in his letter (July 22, p. 128) adopts the attitude that because I am not satisfied with just cleaning the skin I have not an open mind on industrial dermatitis. The whole subject of detergents has been recently investigated in relation to irritants and dermatitis causers, particularly here and in the U.S.A. It may interest Dr. Mummery to know that in many processes, even where tar compounds are used, it is possible to remove the whole of the irritant from the skin without the use of soap or other detergents provided that an adequate barrier has been used. I am not content just to clean the skin after use, as I am of opinion that a disservice is being done to medicine in general, and industry in particular, where adequate preventive methods are not used when such are available. Industrial medicine is a branch of public health, and I cannot envisage any confidence being shown in our work or progress being made unless we take every step to prevent disease of all kinds in industry. Most employers are guided by the advice of their medical officers, and I cannot do better than quote the words of the great pioneer, Sir Thomas Legge (*Industrial Maladies*, Oxford University Press, 1943, p. 3):

"Unless and until the employer has done everything—and everything means a good deal—the workman can do next to nothing to protect himself, although he is naturally willing enough to do his share."

I shall not be content or even proud of my record of two cases in many thousands of workers this year until I have no cases recorded against my factories in any year. Dr. Mummery's own article admits a total in 1943 of 203 cases in 3,850 workers (May 13, p. 660), and I would suggest that he tries all the methods available, and does not rely only upon

cleaning the hands after work. I would point out that the cost of protection with an adequate barrier cream is less than 2d. per week.—I am, etc.,

London, N.S.

L. B. BOURNE.

Chewing-gum or Polypus?

SIR.—Mr. McNeill Love's letter (April 29, p. 600) reminds me of a case I had two years ago in Canada. A sergeant aged 26, a very good technician, reported sick several times with a very vague history of abdominal discomfort. Physical examination was negative. Alkalies had no effect on the complaint, and he continued to smoke and on occasions "go on the beer." It was also discovered that he wanted to get out of the Service. In view of the vague history and the psychological aspects of the case he was considered fit for full duties without further investigations. He was then sent up to the Aleutian Islands, and I was a little surprised to see him back within a month with a letter from his medical officer saying he thought the man had a gastric ulcer. I noticed at this interview that he was chewing gum when he entered my room, but that he was no longer doing so after 20 minutes. On asking him what he did with it he said he must have swallowed it! This time I sent him to the radiologist, making sure that the latter knew the whole history. The radiologist did a barium meal and reported that there was a fairly large filling defect on the lesser curvature in the prepyloric region, and that he thought chewing-gum might be the cause. The same evening, on the sergeant's return, I washed out his stomach with a large stomach-tube, and several pieces of gum were recovered. The treatment was repeated daily for a week, but successive barium meals showed that some filling defect was present at 2 but not at 3 weeks. His symptoms cleared up completely.—I am, etc.,

W. R. DYKE
FLICUT, R.A.F.V.R.

Episiotomy

SIR.—At a London postgraduate course I attended in 1939 the lecturer on midwifery said: "Do an episiotomy in all primips." Since then I have nearly always followed this sound advice, and have always been sorry when I have not, as I have then had to deal with a nasty laceration extending sometimes unpleasantly near the anus, instead of a small clean cut a long way from it. There are points in Dr. Dow's memorandum (June 17, p. 813) and Dr. Barnes's letter (July 1, p. 23) with which I cannot quite agree. Though in theory Dr. Dow's "technique" pictures look like a neat and eminently cosmetic refinement, yet in forceps cases it seems to me there is going to be a rare mix-up around the patient's hinder parts, what with the forceps in position, two pairs of artery forceps hanging down, two loops of sutures getting in the way, and two suture ends doing ditto, the proceedings being illuminated by a nurse holding a torch or by a flaring paraffin lamp on a table perilously near the operator, in a tiny cottage room almost entirely filled by the large bed. But, the woman being under chloroform, what is wrong with a clean cut with sharp scissors at an angle of 45 degrees to relieve a straining and distressed perineum? Half an inch is all that is necessary in most cases to let the head through quickly and comfortably, and anybody who can see straight can sew up an incision like this as well and thoroughly as he can stitch a cut in any other part of the body and with as accurate apposition.

The pundits will probably say I am all wrong, but I often put in the one stitch, or at most two stitches, required before the placenta is expelled and while the patient is still under chloroform. Inspection of the stitch site after expulsion of the placenta has never shown me anything wrong. I should never dream of giving a woman chloroform any length of time after the birth for the sole purpose of stitching her perineum. The G.P. does not give a general anaesthetic to put stitches in head, arm, and leg wounds and cuts; why should he in perineal ones? Two years ago I had three deep sutures put into what is, I suppose, the most exquisitely sensitive part of the body—the palmar surface of my wrist, which was deeply lacerated by a broken bottle—but I never thought of demanding a general anaesthetic. As to Dr. Barnes's "local infiltration with procaine" I should say that the three or four needle stabs required here would be quite as painful as the two caused by a sharp needle and a skilled hand. In "obstetric units," no doubt, the accoucheur is surrounded by willing helpers to run

about for him and hold things. Also he (or she) has plenty of room and light just where he wants it. Dr. Barnes must visualize a dark little room and the conditions described above in place of her nice operating table and impedimenta.

I cannot see why Dr. Barnes assumes, from Dr. Dow's description, that the latter has not "united the deep layers" with his sutures, and accuses him of "merely uniting the mucous membrane of the vagina and the skin of the perineum." Surely Dr. Dow, or any other capable G.P., would naturally insert his sutures through the whole depth of the tissues he was proposing to, or had already, cut. We are not quite so stupid as not to do that.

And what is all this fuss about chloroform? Dr. Barnes says, "It is well known that a parturient woman tolerates a general anaesthetic very poorly," but she must forgive me if I say that exactly forty years' experience of chloroform invariably used without mishap in midwifery compels me flatly to contradict her. Also see Bourne's *Midwifery*, page 96 ("Parturient women tolerate chloroform well"). In the pre-ergometrine era I certainly had occasional qualms in the case of fat flabby women whom I suspected of springing a p.p.h. on me after chloroform, but I was always ready and waiting for this. Since the introduction of intramuscular injection of this product after or (tell it not in Gath!) just before the expulsion of the placenta, I have made it a routine measure in all confinements to give it, with the consequent complete banishment of the boggy of p.p.h. As for any other danger in chloroform in midwifery, there is none unless it is badly given. Since ergometrine, now many years old, I have never seen the slightest ill effect, nor (publish it not in the streets of Askelon!) is there the slightest objection to giving pitocin (not pituitrin, which causes a nasty rise and more than corresponding fall in blood pressure) when the cervix is fully dilated, inertia is present, and you don't want to put on forceps. Pitocin will often bring the head down while you are boiling up your forceps, and save you the trouble, but it should never be used in breech cases.—I am, etc.,

Stowmarket

H. S. GASKELL.

Dentition of London School-children

SIR.—I should like to point out some facts which appear to invalidate many of the conclusions drawn by Lady Mellanby and Helen Coumoulos (June 24, p. 837). These authors compare the dental condition of two groups of 5-year-old L.C.C. school-children in 1929 and 1943. They find the condition in the latter year is the better of the two, and conclude: "It is thought that the observed improvement in the dental condition of this age group may be largely due to the changes in feeding habits which have been developing in recent years—in particular to the introduction in 1934 of the cheap milk scheme of the Milk Marketing Board and later to the wartime food policy, which included (a) increased allowances of milk together with cod-liver oil and fruit juices to pregnant and lactating women, to infants, and to young children; (b) the addition of vitamins A and D to margarine; and (c) the addition of calcium carbonate to bread." The extent to which these dietetic measures could possibly have affected the teeth of children of 5 years of age in 1943 can be judged by considering the following facts:

1. The Milk Marketing Board scheme applies only to school-children; thus the children under discussion can have benefited by it at most for a matter of months before the survey took place.
2. The increased allowance of milk to expectant mothers was introduced on July 1, 1940. Thus it could not have affected children who were 5 years old in 1943.
3. Expectant mothers were first eligible for cod-liver oil on Dec. 1, 1942, which again could not have affected the children in the survey.
4. Lactating women have at no time been eligible for supplies of cod-liver oil or fruit juices. The allowance of milk for nursing mothers was introduced on July 1, 1940; so this, too, is irrelevant.
5. Children under 2 years were allowed cod-liver oil from February, 1942, and children under 5 years from April, 1942. Thus the children in the survey were eligible for only a fraction (and that the latter part) of the first 5 years of their life.

6. The addition of vitamins to all table margarine dates from May 6, 1940. As the paper under discussion states on page 839, the teeth of the children in the survey "were in the main formed in the immediate pre-war years and the first year of the war." Their structure cannot, therefore, have been greatly affected by this measure.

7. Calcium carbonate has been added to flour on a national scale only since Aug. 1, 1943. No statement is made in the paper as to the time in 1943 at which the survey was carried out, but even if it was at the end of the year the calcium carbonate could scarcely have played much part in the dental condition of the children.

In short, whatever the causes of the improvement observed, the dietetic measures mentioned above can have little bearing on the matter. I am indebted to the Rationing Division of the Ministry of Food for confirmation of the dates on which the various dietetic measures were introduced.—I am, etc.,

Oxford.

MARY FISHER,
Assistant Medical Officer of Health.

Syringe for Intravenous Anaesthetic

SIR.—The recent correspondence in the *Journal* about pentothal anaesthesia prompts me to make known this simple apparatus for the intermittent or continuous use of an intravenous anaesthetic.

The apparatus consists of the hub of a needle which is soldered to the open end of a cycle valve, the other end being inserted into a fairly thick rubber tubing whose lumen must

just fit the cycle valve. The other end of the rubber tubing is attached to a glass viewer, one end of which is ground down to fit the needle.

The solution is run through the tubing to expel air bubbles, and the needle is inserted into the vein. The aspiration test is performed by pinching the tubing between finger and thumb, and on release blood will appear in the glass tubing.

The advantages are that the syringe can be disconnected at any time without any return flow of blood, and the needle, in view of this, has very little tendency to clot.

My thanks are due to Mr. S. Yorke, scientific glass-blower to the Chemistry Department of Bristol University, for the glass viewers, which are made from isosal capillary tubing.—I am, etc.,

JOHN A. COCHRANE.

The Services

Temp. Surg. Lieut. E. W. Guillaume, R.N.V.R., has been mentioned in dispatches for untiring devotion to duty in services to the

the Efficiency Decoration has been conferred upon the following members of the Territorial Army: Col. J. Melvin, O.B.E., M.C., Lieut.-Col. (Temp. Col.) E. C. Woodhead, Lieut.-Cols. E. H. Brindle and F. J. Morris, M.C.; Majors (Temp. Lieut.-Cols.) W. A. Ball, W. C. Barber, F. A. Bevan, J. F. Fraser, H. H. Kenshole, and J. K. Reid; Majors E. M. R. Frazer, G. N. Frizell, E. G. Snaith, M.C., and C. N. Vaisey; Capt. (Temp. Major) J. A. S. Brown, R.A.M.C.

CASUALTIES IN THE MEDICAL SERVICES

Killed.—War Subs. Capt. J. P. Hearne, R.A.M.C.

Died.—Capt. J. A. J. Sandilands, R.A.M.C.

Wounded.—Temp. Surg. Lieuts. M. J. Brosnan, W. J. B. Rogers, and A. W. O. Young, R.N.V.R. Lieut.-Col. G. N. Wood; Acting Lieut.-Col. W. M. E. Anderson; Majors P. K. Jenkins, M.C., and E. H. P. Lassen; Temp. Major H. Kennedy; Capt. J. H. Patterson; War Subs. Capt. J. H. Beilby, A. P. Hanway, C. J. R. Jacob, H. I. C. Maclean, K. F. Patton, M.C., T. Savage, M. Taylor, S. D. V. Weller; Lieut. G. R. Connolly, R.A.M.C.

Obituary

SIR ARTHUR HURST, D.M., F.R.C.P.

The sudden death of Sir Arthur Hurst on Aug. 17 has robbed British medicine of one of its outstanding personalities. All his life he had suffered from asthma. For him, as for Lord Chesterfield's son, it was "a troublesome and painful distemper," and it eventually led to his untimely death at the age of 65. Hurst spent his early days in the industrial North and he once told me that it was not till he was 15 years of age that he realized that the trunk of a tree was not naturally black. He was a Demy of Magdalen College, Oxford, and from there he went to Guy's Hospital. Guy's was to remain his great love. He got on the staff at an early age, and he eventually became senior physician. In the last war he was in charge of the Seale Hayne Military Hospital for war neuroses, and after the war he became associated with the New Lodge Clinic. From the beginning of his career he realized the change that had come over clinical medicine, and therefore his private practice as well as his hospital work was based on facilities for accurate scientific investigation. His retirement from the staff of Guy's corresponded with the outbreak of the present war, and, though he continued to visit Guy's regularly, he moved to Oxford and became Radcliffe Lecturer in Clinical Medicine at the wartime undergraduate clinical school. Hurst was editor of the *Guy's Hospital Reports* from 1921 to 1939; he published most of his classical papers there, in addition to important contributions and symposia from his pupils, and he won an international reputation for the *Reports*. He belonged to many societies, and was particularly active in the Association of Physicians of Great Britain and Ireland, which elected him an honorary member to mark its admiration of his genius.

[Wandk]

Hurst's interests in medicine seemed curiously assorted, but there was a unity about them. He began life as a neurologist, and crossed over to gastro-enterology by the bridgehead of pernicious anaemia, subacute combined degeneration, and achlorhydria. His deafness excluded much interest in percussion and auscultation and partly explained the attraction of radiology for him. In psychology he was a pupil of Janet, and a masterly exponent of the treatment of neurosis by persuasion and suggestion. His very success prevented him from seeing the limitations of the method, and he was always a bitter critic of more dynamic Freudian ideas. This was one of the few directions in which he broke no new ground, in spite of the immense amount of good therapeutic work done by himself and his pupils on shell-shocked soldiers in the last war. He was a pioneer in the study of the movements of the alimentary canal in man and the mechanism of pain. His work on the achalasia was highly original, and his conception of rectal dyschezia was an outstanding contribution to the understanding and treatment of constipation. His work on achlorhydria is a landmark in the history of pernicious anaemia and carcinoma. He lived to see his views on the medical treatment of peptic ulcer generally accepted. He "debunked" many mythical maladies; he bravely opposed the mystical nonsense about intestinal intoxication which was so current in his youth, and in his later years he became rather critical of the doctrine of focal sepsis, which he had once himself expounded with enthusiasm. He attracted disciples and fired his pupils, so that his influence spread far and wide. He was unselfish in matters of priority and publication, and much work which did not appear over his name owed its origin to Hurst.

As a clinical scientist Hurst had his faults, and they sometimes annoyed those who did not know him. A cynic once said

that no one ever ate more of his own words, but certainly no one suffered less indigestion in the process. He was almost too fluent in writing and speaking. His mind, like Nature, abhorred a vacuum, and where more cautious scientists would have suspended judgment he would construct temporary frameworks for his thought, which others took for a permanent abode. His surprising *voltes faces* left them puzzled and rather hurt. After almost a lifetime spent in pushing William Hunter's theories on oral sepsis, for example, Hurst turned to extol the importance of good mastication and to deplore the extraction of preservable teeth. Those who knew him delighted in these sudden turns of thought, especially when they had played a part in inducing them. They were another aspect of his plasticity, his receptivity to fresh impressions, his ability to transmit what was new and good in the foreign climes he visited and corresponded with. In Archibald Garrod's words, he radiated lines of force, and whether the effect was positive or negative he was always stimulating.

Hurst was a great character. The careful gait, the bent back, the drawn face, the uplifted hand that cupped an ear the better to listen, the penetrating eye—so well depicted in Herkomer's portrait—the husky voice, the dogmatic utterance that was either "always" or "never," with no penumbra of qualification, all contributed to a personality that strongly impressed the patient and delighted the student. The latter loved to take him off at their Christmas plays, both at Guy's and at the Radcliffe, and no one enjoyed the performances more than Hurst. He never bore malice, was never cross or out of temper. He never bullied a student or a house officer, and there was only one—unbalanced, hypomaniac lad—by whom I ever saw him ruffled. Nevertheless, he had the most devastating mannerisms. His deafness had a selective quality and excluded any sound of contrary opinion, whether it was a patient's objection to a test meal or a colleague's argument against his theories. He commonly sat in the front row at medical meetings. If he was interested, he would crane forward to within a few inches of the embarrassed speaker's face. If he was bored, he would switch off his hearing aid, open his bag, spill his papers over the floor and noisily tidy them up. If he disagreed with the speaker he was not afraid to say so, and would trounce a paper hip and thigh, to the discomfort of the speaker and the delight of the audience. Much of his work was carried out despite a continuous state of asthma. He would arrive at hospital at 2 o'clock and give himself an injection of adrenaline; break away from his ward-round for five minutes at 3 o'clock for another injection; and, finally, have an injection at 4 o'clock before he could make the journey home, white and tired but indomitable.

Hurst was better known abroad than any other English physician engaged in the practice of medicine. He loved to travel, and it is sad that he should not have lived to return, with his band of fellow Medical Pilgrims, to the foreign capitals of medicine. The fertility of his imagination revealed itself not only in medical theory and invention but in the charm and diversity of his devices to promote medical friendships. The last time many of his friends will remember seeing him was a dinner in the summer of 1943, at which medical representatives of all the United Nations were present and Hurst was in the chair. He never swerved from the first rule of the Association of Physicians, whose objects are defined as the advancement of internal medicine and the promotion of friendship among physicians, and he was deeply loved. His wife joined with him in hospitality at their beautiful house in Ascot, a hospitality that was bountifully extended to the stranger and the beginner, and many will remember the gay walks with the children through the Great Park, where the boles were silver and not black, and remembering, they will sympathize deeply.

Topley once said, "If only one could take Hurst's brain and B.'s physique, what a wonderful physician that would make." I think that for once Topley was wrong. Hurst had great gifts. He was a good draughtsman. He was skilful at modelling in clay. He was fond of the theatre. He was a pioneer motorist. He delighted in his family and his home. He had excellent judgment of books, pictures, and furniture, and often spent the half-hour between lunch at the Athenaeum and the ward-round at Guy's visiting the galleries, antique shops, and auction rooms around St. James's Square. But his asthma condemned him to restrict the range of his exertions

and to concentrate on medicine. Without it he might have been more active, but it is doubtful whether he would have achieved as much. Like St. Paul with the thorn in his side, or Darwin with his vertigo, he was spurred to greatness by his infirmity. But paradoxically enough we shall remember his courage even more than his greatness. For many years he was able to gain freedom from asthma in the pure air of the Swiss Alps. It was a great comfort to him to know that he could escape from the oppression of his malady to a life of normal activity in the snow and the sunshine. But in the early 1930's the charm ceased to work. He was asthmatic in Switzerland, and the magic door to liberty was closed. This was a blow to him, but he bore it with fortitude. In the last few years he had not rallied so well from his bad attacks, and had suffered from tiredness and tachycardia. He had so often seemed at the last gasp with his asthma that there seemed no cause for alarm, and the pressure of his work continued unchecked. As on thousands of other afternoons, he sat down for a few minutes to take some adrenaline and recover his breath. And there he was found a little later, where he had died fighting against a life-long enemy to which he had never yielded.

L. J. W.

Dr. WILLIAM JAKES, of Washington, County Durham, who has died at the age of 93, was well known and much respected among the profession in the North Country. The family were of yeoman stock descended from the Huguenots. He was born at Howden in East Yorks, and received his early education at the Grammar School at Malton in that county. In his earlier days he was a chemist, and was more mature than the usual student when he attended the medical college at Newcastle-upon-Tyne, where he was well known among his fellows as an enthusiastic worker, gaining several medals and prizes. After taking his M.B., B.S. at Durham he practised at Usworth, a village about a mile from his old home. Jakes was an example of a type of country doctor that was fairly usual in the Northern coal fields about half a century ago. In the district of Washington, traditionally the home of the De Wessingtons, forebears of the great George Washington, the mainstay for many years has been the collieries and the chemical works, but there was a considerable farming community in the surrounding open country, and one or two big houses. Jakes was the best-known doctor in the village and for miles around, and it may be truly said that the great majority of his patients leaned upon him for advice not only on medical matters but in many of the ordinary affairs of life. In my earlier days in the Newcastle Infirmary some forty-five years ago Jakes was a frequent visitor. He often accompanied his patients, and regularly came to see operations on his cases, and sometimes for no other purpose than to attend a post-mortem examination. This was in the days before motor cars, when the journey of seven miles or so imposed a very considerable demand on his time and energy. In the matter of referring patients to the hospital he set a very good example and followed a practice that might be revived, for he always sent with the patient a careful explanatory letter which was of much value. Jakes was also regular in his attendance at medical society meetings and occasional social functions. He was always keen on his profession and very much alive to the interests of that branch which he so well represented. He conducted a large and extensive practice with the help of a couple of assistants, who always recognized the value of the training they received in that capacity. He had a nice discernment for the coming man, and many of the younger consultants were grateful to him for support in their early days. Jakes was an enthusiastic ambulance lecturer and examiner, and from the time of its foundation was medical officer to Dame Margaret's Home, one of the county branches of Dr. Barnardo's foundation. He was a keen gardener and very fond of books, and was at heart always a student. For health reasons he retired from practice a good many years ago, but his name will long be remembered with gratitude in the Washington district.—G. G. T.

Dr. EDWARD SAMUEL GORMAN, who died on Aug. 11 at the age of 72, had been in practice at Rookery Road, Handsworth, Birmingham, for nearly thirty years. Dr. Gorman was an Irishman who came to Birmingham as a young man, having qualified M.B., B.Ch. at the Royal University of Ireland, Belfast, in 1896. Among the early posts he held were R.S.O., Birmingham Infirmary, and resident medical officer, Birmingham City Fever Hospital. In 1904 he took the D.P.H. Cambridge and was medical officer of health under the local authority at Perry Barr until that area was incorporated into Birmingham. As a general practitioner he was a very busy man, well known and held in affectionate esteem by many.

INFECTIOUS DISEASES AND VITAL STATISTICS

No. 31

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Aug 5.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London), (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1944					1943 (Corresponding Week)

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

EPIDEMIOLOGICAL NOTES

Infestation Control at Ports

At the annual meeting of the Association of Port Health Authorities of the British Isles, held at the London School of Hygiene and Tropical Medicine under the presidency of Alderman W. E. Coupland, an address was given by Mr. W. McAuley Gracie, director of infestation control, Ministry of Food. Mr. Gracie gave a brief outline of the powers entrusted to him by the Ministry. These were contained in the Infestation Order, 1943. Infestation for the purpose of this Order means infestation by insects, mites, fungi, rats, mice, or other vermin, or other animals, plants, or living organisms likely to cause damage to, or deterioration, waste, or loss of, food. He went on to describe the comprehensive treatment of the general London sewer system in December, last, in which it was estimated that 70% of the London sewer rat population were exterminated. This massive operation in London, employing 1,150 men, had encouraged him to initiate similar schemes in the systems of 330 local government districts in densely populated parts of the country. Mr. Gracie then spoke of another important branch of his responsibility—namely, to ensure that food stocks were protected against the ravages of insects. He could not unfold the whole story, but the main lines of treatment were fumigation, spray, and vacuum cleaning, the types of spray being selected for their toxicity to various insects and with due regard to the nature of the commodity to be treated. He said that increasing resort was being made to fumigation of ships' holds to get rid of the endemic infestation of food by insect pests. He added that he had been greatly concerned at the opportunities for slack and inefficient handling of chemicals of an extremely lethal nature afforded by the unregulated state of the industry, and the medical committee of the Association of Port Health Authorities shared his apprehension. He had long felt surprise that it was possible for methods unacceptable in one port to go unchallenged in another. A memorandum on standards for ship fumigation was, at the time he was speaking, under consideration by an interdepartmental committee under the chairmanship of Dr. M. T. Morgan. On the general matter of the licensing of pest control undertakings, an impartial body had been set up to which difficult and controversial cases might be referred for independent advice and to which appeals against decisions might be made. Dr. G. Roche Lynch had accepted the chairmanship of this Advisory Board, and Dr. G. Monier Williams and Dr. M. T. Morgan were the other members.

Medical News

Sir Godfrey Huggins, K.C.M.G., F.R.C.S., Prime Minister of Southern Rhodesia, has been appointed a Member of the Order of the Companions of Honour.

The Trustees of the Dr. Jessie Macgregor Prize in Medical Science announce the award for the present triennial period to Dr. Edith Paterson, F.R.C.P.Ed., of the Christie Hospital and Holt Radium Institute, Manchester, for her work on the influence of wave-length, over-all time, and intensity on radiation effects.

Opening a new maternity unit at St. Mary's Infirmary, Armley, Leeds, Miss Florence Horsbrugh, M.P., Parliamentary Secretary to the Ministry of Health, said that more than 300,000 beds in maternity homes had been provided during the war.

News has been received that Mr. W. C. W. Nixon, who, as announced in these columns on Feb. 12 (p. 242), went to Turkey as medical adviser to the British Council there, has been appointed as attached professor of obstetrics at Istanbul University.

Hofrat Professor Adolf Lorenz, the well-known orthopaedic surgeon of Vienna, was 90 on April 21.

The *Schweizer Medizinische Wochenschrift* announces that a medico-historical institute is to be founded at Bonn University.

A new substance with a texture similar to skin, and flexible and transparent as living tissue, has been produced by Dr. Stanley Tylman, of the Illinois Dental College. It can be coloured permanently to blend with the skin of an individual and finished to a paper edge to hide the union. It is intended to be used, not instead of plastic surgery, but for immediate restoration of missing fingers, noses, ears, etc., so that the injured person can continue normal life while plastic surgery is being planned. The U.S. Office of War Information states that it is the result of more than three years' research by Dr. Tylman, and the possibility of using it for mass restoration of maimed Service men is being investigated.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Autology Westcent*, London. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent*, London.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medusera Westcent*, London.

B.M.A. SCOTTISH OFFICE: 7, Drumshrub Gardens, Edinburgh

ANY QUESTIONS?

Mass U.V.L. in Industry

Q.—Could you publish a statement about the latest opinion on the use of ultra-violet light in factories for employees, especially in the winter?

A.—The latest opinion on the value of mass ultra-violet irradiation in industry appears to range from very enthusiastic, through all intermediate shades, to very sceptical. There is no doubt that, at any rate in the earlier stages of treatment, while interest is sustained, the subjects enjoy it and a fair proportion say that they feel better for it. There is, however, no scientific evidence that this feeling is accompanied by any measurable effect on general health. Scientific observers find great difficulty in forming an opinion because so many other factors are involved. For instance, the worker has been conditioned to regard the rays as of proven tonic value and as a substitute for the blessings of natural sunlight; he feels that something is being done for his health; he gets a break from work; a shower or physical jerks may be used to reinforce the rays; he accepts the suggestion that exposure to the lamps will mitigate the effects of artificial lighting and ventilation—a suggestion which is, in fact, misleading, since even in the best conditions the worker, fully clothed and behind glass, is inaccessible to the shorter ultra-violet rays known to be beneficial in disease, even on the clear bright days of summer, when they do to some extent get through our atmosphere. In response to inquiries from employers and others the Industrial Health Research Board of the Medical Research Council are now carrying out certain investigations, from which it is hoped that, by the use of requisite controls and statistical analysis of the results, some evidence of scientific value may emerge.

Infection with *Oidium albicans*

Q.—What is the best treatment of a vaginal infection by *Oidium albicans*?

A.—Vaginal infection due to *Oidium albicans* usually responds rapidly to local treatment with gentian violet. The vagina should be thoroughly painted with a 2% aqueous solution of gentian violet three times weekly until the condition is cured. So long as the solution does not contain spirit, this painting is quite painless. It is well to continue the treatment after cure is established, and painting should be repeated once in the week after each of the next three menstrual periods.

Myoecrisin for Arthritis

Q.—May I have details of the exact dosage of myoecrisin for rheumatoid arthritis?

A.—A series of observations in America indicated that a lower dosage than has often been adopted in this country was adequate and freer from risk (Freyberg, Block, and Levey, *J. clin. Invest.*, 1941, 20, 401; reviewed in *Ann. rheum. Dis.*, 1941, 2, 279). I adopt the following system: begin with 0.01 g., after 4 days give 0.02 g., and if there is no severe reaction after a further four days give 0.05 g. and continue this dose at weekly intervals till a total of 1 g. has been given, provided that no severe reactions occur. The urine should be tested frequently, preferably before each dose. The sedimentation rate should be tested before the course is started, once or twice during it, and at the end. A full blood count at intervals is also desirable; any decided anaemia or a fall in the number of white cells will indicate the need for caution or for stopping the treatment. Other unfavourable signs will be irritation of the skin, which is as a rule the precursor of a rash usually of urticarial type; but more severe effects such as exfoliative dermatitis and soreness of the mouth may develop, either of which will call for a smaller dose next time, and if the same effect results the treatment must be stopped. Increased joint pains, if not excessive,

are a favourable sign, and a slight rise of temperature is not uncommon; it is wise to have a chart kept recording the temperature and any other effects throughout the course. A second course may be given after an interval of three months. It is not uncommonly the case that any decided benefit is not experienced till the second course is well established.

U.V.L. and Sulphonamides

Q.—I have been told that ultra-violet light treatment is not compatible with sulphonamide therapy. What is the reason for this if correct? I have a patient aged 7 on continuous 0.5 g. twice daily doses of sulphonamide who has also derived much benefit from U.V. light treatment, but can both be employed concomitantly?

A.—The only sense in which ultra-violet light and sulphonamide treatment are incompatible is that these drugs have been found in some individuals to cause the liberation of photosensitizing pigments: a drug rash may therefore occur during treatment in areas exposed to sunlight. This distribution is by no means invariable, nor is any rash, whether confined to exposed areas or not, a common consequence of sulphonamide treatment, particularly in moderate dosage. If, therefore, both treatments are indicated, they may safely be undertaken together, the only risk being a small chance of producing a rash.

Wasp and Bee Stings

Q.—In this part of England the wasps are in great numbers this year, and stings are frequent. Is any local treatment useful; if so, what? Is there any virtue in the extremely popular remedy, washing blue? Is it rare for general reactions to occur after wasp and bee stings? What is the actual difference between the stings of the bee and the wasp? Are they both formic acid? In one case of wasp sting I was called in to, the girl fainted twice and had felt very ill. One dose of sugar and sodium bicarbonate seemed to produce an immediate improvement; is this rational?

A.—The stings of wasps and bees are rather similar in general structure, one important difference being that the bee sting is barbed and not easily withdrawn like that of the wasp; consequently the whole apparatus of sting and poison glands is usually torn from the bee abdomen. Since the poison sacs remain attached, the "sting" should be removed at once.

The venom of the bee sting is unfortunately not a simple chemical like formic acid: it is a mixture of several substances, including histamine and a toxic protein of low molecular weight, "apitoxin." Less is known about wasp venom, but from the affinities of the two insects and the similarity of the sting mechanism it seems probable that this is a mixture of the same type.

After a sting there is a cutaneous reaction which is probably due to the histamine, and in addition there may be a general reaction caused by the toxic proteins, especially if the sting happened to penetrate a vein. It is difficult to see how local treatment with acids or alkalis can alleviate the pain, though the application of any damp cool substance might be analgesic. In general one can only say that treatment should be symptomatic.

Hours of Rest for Adolescents

Q.—Should healthy adolescents (school or university) be discouraged from regularly spending 10 to 12 hours or more in bed during their holidays, or not? The question has no particular reference to wartime.

A.—I do not think this question can be answered without particular reference to wartime, as all the adolescents have grown up in five years of war. Present conditions make great demands on senior boys in schools and young men at the university. Not only do they have their ordinary work and examinations and their games but also strenuous O.T.C., preparing for certificates A and B, and nearly all of them have helped in agricultural work and in some share of domestic duties at school. They have much less fat for energy and much less protein for body-building in their diet than in peacetime. I think they should be encouraged to spend 10 hours or more in bed during at least their first fortnight of holiday, and probably for longer if the strain has been considerable. No recent writer has improved on Clement Dukes of Rugby, who in 1894 (*Health at School*, Livingtons) said: "The tendency . . . is rather towards too little than too much sleep; in fact in public schools, generally, I think the boys are rarely allowed sufficient sleep, especially the younger ones; and were it not for the holidays every 12 or 13 weeks, they could not do their full share of work and continue in health . . . all schools suffer from this deficiency more or less. Parents are only too cognizant of the fact during the first few days of the vacation, and are apt to think that their children will become sluggards; while in reality they are only making up for lost time. I lay great stress on sufficiency of sleep."

Clement Dukes gives the following suggestions for adolescents' hours of sleep: "Under 15: 10 hours (9 p.m. to 7 a.m.); under 17: 9½ hours (9.30 to 7); under 19: 9 hours (10 to 7)." I think, at the

beginning of the vacation—i.e., the first fortnight—at least an hour and preferably one and a half hours should be added to these numbers of hours to make up for lost time. I think the same remarks apply to girls.

Vaginal Discharge

Q.—A woman of about 30 has, for an indefinite number of years, had a vaginal "discharge" which stains her underclothing brown on its exposure to air, and the fabric is eventually destroyed by the erosive action of the efflux. Since her first baby this state has become worse. She has no vaginal discharge in the ordinary sense, though her labiae are moister than normal. Her health is excellent. Examination reveals nothing. I would appreciate a few pointers.

A.—Even though it is not obvious on examination, this patient must have a discharge to produce this staining of the clothing. Vaginal discharge which is white or cream in the fresh state not infrequently leaves a brown stain on drying. Intermittent escape of urine (stress incontinence) should be excluded, but the most likely cause for this symptom is a lesion of the cervix—erosion, cervicitis, or endocervicitis. This suggestion is supported by the fact that the condition has been made worse by child-bearing. Full examination of vaginal swabs is indicated and also careful inspection of the cervix, followed possibly by treatment with cautery or diathermy.

Telegony

Q.—One has heard it said as a truism that a pure-bred bitch, if crossed by a dog of another breed or a mongrel, is thereafter useless for pure breeding by a dog of her own breed. It is said that there will be a taint of the other breed even if her puppies are by a dog of her own kind. Is this really so, and if so, is this rule applicable to human beings after a woman has a child by, say, a negro?

A.—A belief in this phenomenon, to which the term "telegony" has been applied, is probably as old as the art of stockbreeding itself. Until comparatively recently it would have been a perfectly reasonable belief. The critical mind of Darwin was satisfied as to the reality of telegony by certain observations, notable among which was the classic case of Lord Morton's mare. This animal, of almost pure Arab blood, was mated to a quagga, a kind of zebra which is now extinct. Mated on two subsequent occasions to a pure Arab stallion, she produced two foals with clearly striped legs and the short, stiff mane characteristic of the quagga. Much later (1896-1901) the experiment was reconstructed with great care and on an ample scale by Coscar Ewart. No evidence in favour of telegony emerged. Darwin had been misled by chance throws of the hereditary dice box; it is, in fact, not very unusual for ordinary foals to be born with stripes. No evidence for telegony has ever appeared in many other carefully planned experiments in which there should have been every chance for its occurrence. At the present time, however, it is possible to go further. Not merely is there no scientific evidence, but enough is now known of the mechanisms of reproduction and heredity for us to be sure that there never could be; it is impossible that the phenomenon could occur. A belief in telegony was not unreasonable in Darwin's day; at the present time it is wholly inadmissible. But it is a superstition which is dying very hard. (For an interesting account see Crew's *Animal Genetics*, Edinburgh, 1925.)

INCOME TAX

"Pay as you Earn"

W. B. has taken on work as an "indefinite locum" with possibility of a death vacancy transfer.

** Normally a locumtenent holds a particular engagement for a short period and holds several in the course of a year. In such circumstances the earnings are usually assessed under Schedule D and do not come within "pay as you earn." W. B.'s position, however, appears to be different; he is in effect a temporary assistant employed by the proprietors of the practice, and "pay as you earn" applies.

Assistant's Board and Lodging

K. S. is employed as an assistant. His employers have themselves, out of their own pocket, defrayed his board and lodging expenses first when he resided with them and afterwards at his present residence. The inspector of taxes contends that he is liable to assessment on the £150.

** In our view the question of liability depends on the precise nature of the arrangements made. Non-liability does not attach only to board and lodging under the principal's roof; it applies if the assistant is boarded elsewhere. But if the facts are that K. S. is liable to his landlady for whatever amounts may be due to her, and the employing firm pay his debt for him, then it would seem that the discharge of that debt is equivalent in effect to paying the amount in cash to K. S., and he is liable to assessment to income tax thereon.

LETTERS, NOTES, ETC.

Wanted for Research

Prof. F. C. PYBUS, F.R.C.S., writes from the Royal Victoria Infirmary, Newcastle-upon-Tyne: I am working at the cause of mammary carcinoma and have been feeding some mice of non-mammary carcinoma strain with human mammary carcinoma, which may be supposed to contain the "mammary factor" if the cause is the same in man as in mice. A more direct experiment would be the feeding of some young mice with the milk of a woman who has, or has had, a mammary carcinoma. Such cases are, of course, uncommon, and I am asking your help to get in touch with a doctor who knows of one.

An Appeal to Good Nature

Owing to the need for severely restricting circulation of the *Journal* while the paper shortage lasts, a number of institutions and individuals connected with medicine and its ancillary services can no longer obtain the weekly copy for which they formerly subscribed. Any member who might be willing to pass on his *Journal* after reading it (making himself responsible for dispatch and postage) would be given the name and address of a suitable recipient if he wrote to the Publishing Manager at B.M.A. House, Tavistock Square, W.C.1.

Molluscum Contagiosum

Dr. AGNES SAVILL (London, W.1) writes: Regarding the case of molluscum contagiosum for which advice was asked (July 15, p. 101), in my experience recurrences point to the existence of an infecting object being employed, such as a sponge, loofah, favourite facecloth. In one case a special hat-band conveyed the infection. If this is carefully investigated and the offending object destroyed, recurrences should cease.

Pest of Flies

Lieut.-Col. R. M. BARRON, I.M.S. (ret.), sends the following suggestions for dealing with flies: "Breeding places outside houses should be searched for, and, if found, dealt with. Flies enter a house on the sunny side to find food and drink and to obtain shelter from the sun. Windows and doors on which the sun shines in the morning should be kept closed while the sun is on them; the windows and doors on the opposite side may be left open. In the afternoon the windows and doors on the sunny side of the house should be closed, and those on the shady side opened. An hour before sunset all windows and doors may be opened, for if some flies have entered to obtain protection from the sun and to obtain food and drink and have found none they will fly out for a further search. These facts can be strikingly observed with tents, especially in the desert, but by following the same rules the nuisance can be greatly avoided. Fly traps may also be used. Portions of net, with meshes as large as those of fishing nets, hung over doors and windows of houses or the entrances of tents will keep out flies.

Genesis of Shock

Capt. BRANDON LUSH writes: The interesting article by Major Charney (May 27, p. 716) throws fresh light on the genesis of shock. It shows that, under anaesthesia, local fluid loss is the most important, if not the only, factor in the production of shock. However, the casualties we see are conscious (shock is slight or absent in head injuries) and able to suffer pain. G. W. Crile years ago realized the importance of pain in the genesis of shock and used local anaesthesia (especially nerve-block) to combat it. I feel that pain is the most important factor in the genesis of shock—hence the value of morphine in prophylaxis and treatment. All attempts to reproduce clinical shock by experimenting on animals under anaesthesia are likely to be fallacious. I believe that (references are unobtainable in the field) trauma to a limb rendered anaesthetic by local anaesthesia or nerve division produces no more shock than that expected by fluid loss. Charney's article also reminds one of Patey and Robertson's suggestion of tight bandaging of a limb to prevent the onset of the crush syndrome.

Corrigenda

Sulphapyridine in Bacterial Endocarditis.—The course of sulphapyridine given to the patient in the case described by Dr. R. P. Lawrie (Aug. 12, p. 224) consisted of 12 g. (24 tablets each of 0.5 g.) and not 0.12 g. as stated.

Registration of Specialists.—The first line of Dr. A. Piney's letter (Aug. 19, p. 253) belongs to Capt. Jacobs's letter on page 254. Dr. Piney's letter (dated Aug. 5) should begin: "The current issue of the *Journal* should, I think, be read," etc.

Disclaimer

Dr. V. N. LEYSHON, Deputy Medical Officer of Health and Tuberculosis Officer, Blackpool, asks us to state that he disclaims any knowledge or participation in the publication of an article in various Sunday newspapers of Aug. 6, 1944, in which his name appeared.

BRITISH MEDICAL JOURNAL

LONDON SATURDAY SEPTEMBER 2 1944

SOME GENERAL CONSIDERATIONS ON HIGHER OR POSTGRADUATE MEDICAL STUDIES

BY

F. M. R. WALSHE, M.D., D.Sc., F.R.C.P.

A far-sighted and comprehensive outlook upon the problems of higher or postgraduate medical studies is not less vital to the future of medicine at this juncture than is a sound and liberal regime of undergraduate medical education.

In a recent article in the *Journal*¹ I ventured to discuss what appeared to me essential defects in the methods and content of our undergraduate teaching, and in some of the schemes proposed for its improvement. The difficulties in respect of higher medical education, if somewhat different and less obvious, are nevertheless real and pressing, and their consideration is complicated by diversity of view as to what we are to include under the title of postgraduate education. Some attempt at definition is clearly necessary, but in the meantime, however we define their scope, higher medical studies present us with a current problem of the first importance. Whatever form the medical services in this country may ultimately take, they will make heavy demands on the services of consultants and specialists, and while the proper Government authority will doubtless enter with zest into the organizing of doctors within the framework of a medical service, the adequate training of those doctors for the diverse functions they will have to undertake within such a service, and the maintenance of professional standards, are responsibilities we dare not delegate to the service is to become in fact what it should be. That this task is recognized as ours finds a welcome confirmation in some remarks of the Prime Minister, recently made at a luncheon of the Royal College of Physicians (see *Times*, March 3), when he expressed the desire that there should be no lowering of consultant standards in the manning of the future medical services. In short, the intellectual traditions of medicine thus rest in our hands, and their maintenance and enhancement rest on our responsibility. These, we shall have to remember, will go far beyond the immediate utilities of any national medical service.

We may therefore proceed to consider the aims and methods of higher medical studies, and the nature of the institutions in which they may most fruitfully be pursued.

Role of the Special Hospital and Medical School

While the main academic preoccupation of the great teaching hospitals must remain the training of undergraduates, higher medical studies and research will inevitably continue to be conducted within them, and if the number of whole-time professors and teachers is to be increased it may be hoped that these vital activities will multiply. It is probable, however, that the precise nature of the studies thus followed at any one will depend upon the interests of the then holders of professorial chairs and their teams of workers, and there are special branches of medicine—e.g., neurology, dermatology, radiology, etc.—the development of which cannot be left to chance in this way, but must be pursued methodically in adequately staffed and equipped special hospitals and schools of medicine is to advance on all fronts.

Nevertheless the view has been authoritatively expressed that the day of such hospitals and schools has passed, and that the special branches of medicine may best be developed in the

special departments of large general hospitals. This view is strongly contested here as the product of the organizing mind, concerned only with administrative tidiness and ignorant of the scientific and cultural issues involved. The development of specialization in medicine is inevitable and will be progressive, like it or not as we may, and if every undergraduate teaching hospital is to set up the requisite number and variety of special departments, adequate to conduct high-grade postgraduate teaching and research, the multiplication of hospital and laboratory accommodation and facilities, and of personnel, will be enormous and the multiplication of effort and expenditure wasteful in the extreme—and all this with a quite disastrous loss of efficiency.

In every developed special branch of medicine there must surely be a central hospital and institute that shall form the growing point of knowledge in its special field. Here can be gathered with the greatest economy and efficiency the essential clinical and pathological material and full facilities for its exhaustive study. Moreover, a specially trained group of workers all pursuing knowledge in the same field of medicine within the walls of such an institution will enjoy the stimulus that a team can alone provide and that is so vital to the fruitful activity of the scientific worker.

On the other hand, the one or two men staffing the small special department of the general hospital must perforce work in comparative intellectual isolation, nor can they possibly command the material resources of the central institute.

It is therefore submitted that any attempt to disperse such schools and to divide their activities among a group of general hospitals would be a retrograde step gravely adverse to the future of medicine in this country. Special research and the adequate training of specialists can be competently undertaken only in the special hospital and its attached school.

There is also an essential place for the special postgraduate school not confined in its activities to any special aspect of medicine, but free to cover all fields both in research and in the promotion of higher studies. The British Postgraduate School in London already fills this role, and it may become expedient in time to found comparable institutions in other great centres of medical education throughout the country.

The Aims and Methods of Higher Medical Studies

There appear to be some who view the postgraduate school mainly as an institution for the provision of what are euphemistically called "refresher courses" for general practitioners, or, in the near future, for young medical officers to be demobilized from the armed Forces and contemplating a first entry into civilian practice. The value of such courses as a long-term policy is dubious; but, however we view their potential usefulness, it is surely clear that their provision, as an exclusive function of a postgraduate school, expresses an impoverished conception of what such a school should occupy itself with. This provision by no means exhausts its proper functions, though it may easily exhaust the staff. There is also to be considered the provision of opportunities of all necessary kinds for the research workers of the future, and also of facilities for the training of consultants and specialists—functions that are not wholly identical. It is here submitted that

¹ "Some Principles of Reform in Medical Education," *British Medical Journal*, Feb. 5, 1944

the primary and essential role of a good postgraduate school consists in the provision of a fair field of facilities, and in the creation of a favourable atmosphere, for advanced and original studies. I should therefore put in the following order of importance the functions of a postgraduate school of medicine: (i) the provision of opportunity for research and the advancement of knowledge; (ii) the training of specialists and consultants; and, questionably, (iii) the provision of "refresher courses." The qualification inserted under the last heading is not to be taken to imply that a postgraduate school has no responsibilities towards the general practitioner, but it expresses the grave doubt as to whether the refresher course itself is the proper way in which this responsibility should be discharged, and as to whether this type of course—if its usefulness be conceded—should be undertaken in a school where really advanced studies are pursued. Indeed, my own view is that these two activities—advanced studies and refresher or examination courses—are incompatible in a single institution; for experience, as will later be indicated, has so far shown that the latter tend to destroy the former.

Research and the Advancement of Knowledge

It is possible that some may be impatient with the notion that these really are the primary functions of a postgraduate school. Issues of more pressing importance, such as the early provision of consultants and specialists, may appear to demand priority. This question involves our entire outlook upon what should be the training of these categories of doctor. Few will dispute that a purely teaching institution wherein no one is engaged in the forging of new knowledge, or in thinking on broad lines about the problems of medicine, but where all are occupied with the handing on of established knowledge and the imparting of techniques, is a dead school. At the best it is merely a polytechnic primarily devoted to grinding out courses for this or that specialist diploma. Research and the advancement of knowledge not only serve the ends indicated by their names, but they also provide—and can alone provide—the keen and critical atmosphere in the absence of which we cannot hope to train specialists of the first rank. It is therefore urged that original thought and work are vital elements in the life of any school for higher medical studies, whatever else we may ask of it. Surely, also, now is the time to approach the new medical world opening before us with the highest possible ideals, for the dangers to idealism and enterprise in any State service that is based on an immediately utilitarian point of view cannot be discounted by the most ardent champions of the reorganization of the medical profession.

In an earlier article in the *Journal*,² entitled "Strategy and Tactics in Research," I ventured to discuss some of the defects in our present outlook upon research problems, and, while I do not propose to weary the reader with recapitulation, some considerations may be restated. The deep searchings as to the very bases of scientific thought that have stirred the world of physics within recent years have had little echo in the world of biology, including physiology and medicine, and we are in some danger of losing sight of first principles of science in our growing preoccupation with experimental techniques. These are now so ingenious and have proved so valuable in the opening up of fresh fields of discourse about medical and physiological problems—as, for example, in the case of the elaborations of electrophysiology—that not rarely we fail to see the wood for the trees. As techniques multiply and grow more specialized, so width of comprehension shrinks. There develops in consequence the tendency to consider research as adequately conducted by the recording of random observations obtained by the use of new techniques, without further consideration of their wider import and relationships. Science thus comes to be viewed as consisting in mere observation and the accumulation of records, without the generalizations and hypotheses and other intellectual instruments that can alone transform information into knowledge and thus lead to advance. The perusal of current physiological and medical journals reveals that a large proportion of their contents consists of these isolated items of information, and the author, especially if he be young, who ventures daringly to attempt some

generalization or synthesis of his findings with those of other workers is in danger of having his contribution declined.

There is, it seems, a pervading intellectual timidity or shyness that shrinks from original thought and, in effect, discourages adventures of ideas. Yet, as Whitehead has remarked, "Part of error is the death of progress." This situation has been candidly summed up by another philosophical writer of to-day thus: "There is little hope of the good scientist, who is minded to his specialized business, devoting himself to the broken foundations of his science; it would only be bad betting for him as an individual to give up his time and energy to a critical and general speculative investigation, when he has before him the possibility of pushing his specialty a few solid steps ahead. Such a state of affairs is plainly as adverse to true advance as the opposite extreme of unbridled speculation, and we should not remain content to ask of a man what 'discoveries' he has made; we should also proceed to inquire of him what he has made of his discoveries, or, for that matter, of anyone else's."

It should not be too sanguine to hope that we shall in future see at least some centres of higher medical studies that will set themselves to break with this timorous tradition, and will attempt, as among their ideals, the ordering of knowledge and the training of men in the basic principles of scientific thought. At no time in the history of medicine and its daughter science has a deeply thoughtful attitude to research been more imperative than it now is, and it is this conviction that must be the excuse for a digression that may have seemed to the reader of undue length and doubtful relevance.

The Training of Specialists and Consultants

The wisdom of undertaking this training in institutions wherein original thought and work are actively pursued has already been discussed. In no other way, save by such contacts, can the student be fired to undertake original work himself. To see knowledge being won is, for those who have it in them, the adequate stimulus to add to knowledge. Yet this need not be taken to imply that every would-be specialist or consultant should be expected as a matter of course to undertake research. A man may have the making of an excellent clinician and an admirable teacher without also having a flair for original investigation. This may seem obvious enough, yet the notion encounters some opposition largely from those who like to sentimentalize research as something inherently virtuous by participating in which we must all be the better. Yet research is a means and not an end, and there is no doubt that hitherto a young man hoping to make a place for himself in clinical medicine has found himself under the necessity of "going through the movements" of doing research, and the publication of an "original paper" has been widely taken as a test of his capacity. Thus it is that medical literature has been burdened with far too much inferior matter in order that men may obtain due recognition of gifts and attainments in quite another field of medical endeavour. Against this danger it is to be wished that the postgraduate school of the future may be on its guard. Gifts for teaching and for research are not necessarily combined in a single individual, and generations of science and of medical students have suffered from the popular and eminently respectable illusion that a distinguished scientific investigator must necessarily be fitted to teach the elements of knowledge in his own field. Nevertheless, the original thinker and worker is a heaven vital to the fruitful activity of every medical school, even though not all teachers or students need be expected to follow in his footsteps.

The Role of the Special Diploma

The training of the specialist needs to be both theoretical and vocational, covering both a science and an art of medicine. What is implied by this has already been discussed by me in a recent article on the reform of medical education and need not be further elaborated here. The detailed curriculum of studies essential to the full training of the specialist and consultant also need not be minutely discussed. We may, however, make some mention of the specialist diploma examination as a criterion of competence in the field of medicine.

² Scott Buchanan, *The Doctrine of Signatures: a Defence of Theory in Medicine*. Kegan Paul and Co., London, 1933.

Within the past few years the number of these diplomas has increased considerably, and the Royal Colleges in this country now grant no fewer than nine, not to mention those given by universities. As to their influence upon those postgraduate schools that provide systematic courses for them, it can scarcely be denied that it is wholly adverse—that is if we accept the conception of the postgraduate school herein submitted. Schools making the provision of the necessary courses a primary activity end by doing nothing else, and their research activities dwindle and die. It would be invidious to seek to exemplify this proposition, but the case may be presented in another way. So far, happily, there has been no specialist diploma in neurology, and up to date the primary aims of the postgraduate school attached to the National Hospital for Nervous Diseases at Queen Square have been to conduct original research and to provide a sound all-round training in clinical neurology and neuropathology to its students, the reward of the latter being the work they had done and the experience they had acquired, and not any label or diploma granted to them. It is interesting to note that this school is the only one of its kind in the country to which, right up to the outbreak of the present war, there was a steady flow of serious postgraduate students from the Dominions, America, and Europe—men and women of professional and other university status desirous of higher training. At a period in the history of medicine in these islands when, owing to the rapid development of medicine in the United States and the Scandinavian countries, the flow of graduates of this type to this country has virtually ceased, this is a remarkable tribute to a school that has been interested in a culture rather than in a curriculum, in a discipline rather than in a diploma. It is not implied that distinguished leaders in medicine and physiology in this country have not continued to attract pupils from abroad, for we know that they have done so but that no other postgraduate school as such, has commanded the reputation requisite to bring graduates of the best type and in considerable numbers to these shores.

While, therefore, the special diploma can hardly be regarded as an inspiring stimulus to, or end of, higher medical studies, it possibly has certain useful though restricted purposes. For example, it may assure a working level of efficiency in such special techniques as those of radiology or anaesthetics, and where a large medical service, such as that of mental hospitals or of tropical medical services, requires large numbers of medical officers, the special diploma course ensures that they acquire an adequate familiarity with the branch of medicine in which they intend to practise. But all this is quite another thing than the acceptance of such a diploma course as adequate to the assumption of consulting responsibilities. There require a deeper foundation of experience in general medicine than the special diploma demands or its curriculum provides.

As an element of value in higher medical studies designed for the training of specialists or consultants there are other and more positive defects in the special diploma, as we know it. It tends to focus the candidate's attention upon a curriculum rather than upon the full range of the subject. It promises to better higher medical studies, which are best pursued for their own sakes, in the shackles of the examination system—with us a purely vocational system with no theoretical background, and finally if the special diploma were ever to be accepted as a criterion of consultant status in a highly organized public medical service, it would lead to arbitrary and unworkable restrictions upon consulting practice. Thus, how fantastic it would be though by no means impossible, if no one but the holder of a diploma in psychological medicine were to be permitted to deal with, or to issue certificates in respect of, cases of psychoneurosis, or cases in which a prominent psychological element was present! Such cases, as we all know, loom large in the experience of consultants in every field of medicine, coming disguised as somatic disorders involving the nervous system and every possible organ. Further, a concept of psychosomatic medicine is now being developed which proposes psychological factors of causation for a wide range of somatic illnesses. The practice of medicine would become impossible if all consultants were to be restricted by artificial barriers within the field of medicine, and the general level of medical efficiency would inevitably deteriorate.

The truth surely is that the special diploma tends to breed technicians and not physicians; individuals better able to apply techniques than to make those essential clinical assessments that alone render the employment of techniques, be they of psychology or of bacteriology, a rational activity. It is in the field of therapy that their influence is most baneful. Treatment should be thought of as a whole, "as the total contribution of the physician to the complicated action that is taking place within the patient incessantly." It should not be thought of in isolated categories or in terms of specific instruments or aims. "Therapy is one of the routes by which medicine has been specialized, and by which the specialties have become vicious" (Scott Buchanan, loc cit). A final question arises. The special diploma makes no adequate provision for the postgraduate training in general medicine of any aspirant to consultant status. Hitherto the experience needed by the candidate for the London M.R.C.P. has usefully served to ensure this, but if the easy key of the special diploma opens the door to consultant work, who will trouble to acquire this essential foundation of clinical experience? This examination will fall into desuetude, and our standards will fall with it.

The Value of Refresher Courses

Possibly, an equally controversial issue with that just dealt with is provided by the question of the value of the so-called refresher courses. These attempt the impossible—namely, the imparting in too brief a space of time to tired, or even unsuccessful, men of a range and quality of knowledge that cannot be transmitted in this way. As a mode of instruction in specific techniques of diagnosis or of treatment they may have a limited scope of usefulness, but of general cultural value little or none. At best their influence can be but transient. Surely the remedy for the inevitable difficulty of keeping abreast with advances in knowledge and techniques—as this has obtained hitherto under the common conditions of general practice—is not the makeshift expedient of a brief refresher course, but such a replanning of the conditions of general practice as shall prevent the isolation of the doctor and shall keep him in constant touch with hospital and specialist services throughout his professional life. Some such arrangement should be an integral part of any planned medical service. But if the brief and rarely repeated short cramming course is to be retained, then its provision cannot be a function of such a postgraduate school as has been here discussed. The medical staff of such a school could not possibly stand up to the unremitting repetition of such courses without becoming spiritless hacks, and all their more vital activities would inevitably go to the wall. There would have to be organized special institutions for this work, which cannot be combined with the pursuit of higher studies in medicine. It is to be hoped, however, that nothing of the kind will be found necessary in a better-planned medical world.

Conclusions

We may easily, at this juncture, aim too low in our plans for the future of higher medical studies, but we cannot easily aim too high. No craven fear of what official organizing zeal may do to us while we are seeking to maintain our standards, or even to enhance them, should lead us to fall short of our traditions. We still have freedom to think about the future of medicine, and this should not come to be construed as freedom not to think. If we set to work now in earnest there should be ample time, while an agreed form of medical service is being hammered out and then begins to grow, to produce the right type of specialist and consultant and the numbers we shall need of them. We have in fact, in the Prime Minister's speech earlier cited, been invited to maintain our standards.

In assessing what should be the criterion of an adequate specialist and consultant training we shall do well to rely mainly upon securing full opportunities for higher studies, and for research for such as have the gift for it, and upon judging men by their work and achievements during their period of training rather than by the hazards of a postgraduate diploma mill. After all, the great names in medicine are those of men who trained themselves after graduation and owed nothing to educational planning. It is clear, of course, that such a diploma system would make the task of the official "grader" of consultants delightfully easy, for it would provide him with those

paper categories of doctors which would be as useful to him—if not to the community—as a really adequately trained body of consultants. Yet it is not our business to turn out numbers of mass-produced "utility" consultants and specialists just to make an organizer's paradise, but to see to it that the community gets a service worthy of us.

So far the examination system has not imprisoned higher medical studies irrevocably in its paralysing grasp, but we shall need all our vigilance to see that it does not. I will go even further. In the past we have not seldom lost for medical science men of outstanding ability because they did not, at the appropriate time, acquire those alphabetical adornments to their names that we have asked of those to whom we have offered opportunities in consulting and academic medicine. This should not be. Surely in a liberal profession based on science there should be a career fully open to talent. Nothing is better calculated to obstruct this than a barrage of diplomas.

THE USE AND ABUSE OF TRICHLOROETHYLENE

BY

G. E. H. ENDERBY, M.B., B.Chir., D.A.

Anaesthetist, E.M.S.

"In estimating the untoward effects of any anaesthetic agent three factors are always involved—(1) the anaesthetic agent, (2) the patient, (3) the anaesthetist—and only too often the last of these factors is ignored."

Trichlorethylene, a comparatively recent addition to the anaesthetist's armamentarium, has in the last two years come into fairly wide use in this country, and was at first received with applause and thanks for an agent with many useful and unique qualities. The initial enthusiasm, as is so often the case, was soon replaced by an equally severe swing of opinion to the other extreme, in which all its bad qualities and dangers were repeatedly emphasized. It is this latter swing which occupies the pages of so many contemporary journals, and this article has been written in an effort to control and in part to prevent any undue bias, and at the same time to present material from which a more balanced evaluation of this agent can be made. So much that is good can be hidden by a little that is indifferent, and so many are easily biased by the chance observation of a headline, the remarks of a colleague, or even the smell of a particular anaesthetic.

Langton Hewer (1942) first brought his careful investigation of this agent before the Royal Society of Medicine, and in that report gave particulars of its chemistry, physical properties, and anaesthetic quality. No further mention will be made of these particulars, but attention will be focused instead on the use of this agent, with special reference to its limitations and to the bad effects of ignorance and misuse.

Apparatus

It has become customary to place the trichlorethylene in the chloroform bottle of the Boyle apparatus. This practice is convenient, but at the same time affords scope for a grave abuse of the agent, for only too often the *minimum* which such a bottle will allow proves to be too great for maintenance of the patient, whereas any approach to full delivery, with gas bubbling through the liquid, gives a higher vapour concentration than any patient ever requires. Here then lies a danger, and one into which fall so many who are not conversant with the small amount of trichlorethylene that is needed. It can be stated with confidence that very few patients require more than the minimum vapour flow from such a bottle, and indeed this may often prove an overdose. An extremely small percentage receive the full flow with the plunger elevated to the top, and never has it been found necessary to increase the vapour concentration any further by lowering the plunger towards the surface of the liquid; but on many occasions I have observed administrators labouring under a full load of trichlorethylene, with a difficult patient showing a respiratory rate of 60 to 80 a minute. These administrators, too, are the first to complain about the "disadvantage of trilene" in raising the respiratory rate!

Thus the type of apparatus commonly employed is one reason for misuse of this agent, and for a considerable period a drip-feed of the vinesthene pattern was employed instead. This works very well, but the property of trichlorethylene of dissolving fats so readily soon makes all the joints leak, and the apparatus becomes dirty and wasteful. Furthermore, vaporization in the stream of cold gases is difficult. However, it is felt that some device constructed along these lines, by which a very small minimum dose could be given, or alternatively a well-designed vaporizing bottle for the Boyle machine would be a considerable help in avoiding overdose. Marrett's trichlorethylene-air apparatus has bottles which allow good vaporization of the liquid, and it appears possible with this apparatus to obtain the small minimum dose required.

Induction and Depth of Anaesthesia

Induction with trichlorethylene is difficult, and it is here that trouble may arise, for in attempting to obtain the requisite depth of anaesthesia there is a tendency to use more and more of the agent. This increase of vapour concentration rarely brings with it the desired diminution of muscle tone, and this, when it was first used, seemed to be a great drawback and disappointment. However, it was soon appreciated that other agents can be easily employed to carry the patient smoothly and quickly into the third stage and to obtain the desired relaxation; the further course of the anaesthesia can then be conducted smoothly and without incident under trichlorethylene. Once the necessary relaxation has been obtained and the stage of surgical anaesthesia reached, this state can be maintained indefinitely on a minimum of the agent, which suffices to hold a steady plane of anaesthesia showing little tendency to change. First-plane anaesthesia is the usual level, though an occasional patient shows signs of the second plane; and it is fortunate indeed that the lighter plane is sufficient depth for the performance of the overwhelming majority of surgical operations. With trichlorethylene it is as a rule impossible to obtain the deeper levels of third and fourth planes, and the recognized signs associated with those levels are certainly not observed. Any attempt thus to deepen the anaesthesia usually meets with one or other of two conditions—(1) a rising respiratory rate, or (2) sudden respiratory arrest. In other words, trichlorethylene has a very limited working range; but for reasons previously stated this is a most useful range, and, furthermore, physiological disturbances occur with considerably less frequency in such lighter planes.

For convenience, and where a barbiturate is not contraindicated, pentothal, or some similar rapidly acting intravenous anaesthetic, is employed for induction, and is followed by nitrous oxide and trichlorethylene on the Boyle machine. The necessary relaxation is provided by the barbiturate, and if sufficient has been given to tide over the time required for the introduction of the trichlorethylene, then such relaxation is maintained for the duration of anaesthesia, and a quiet smooth anaesthesia results. In cases in which a barbiturate is not desirable, or is contraindicated, the induction is made with nitrous oxide, followed by a little oxygen and then trichlorethylene. Cyanosis is avoided, as this tends to persist under trichlorethylene even with an ample sufficiency of oxygen. With adequate well-timed premedication it is possible to produce the necessary relaxation under nitrous oxide and trichlorethylene alone, but in 50% of cases muscular relaxation under this agent is still not adequate—i.e., arms and legs are usually stiff, and vague wandering movements are to be seen in fingers and wrists and feet—and small quantities of ether have to be added to produce it. The very small amount of ether required at this stage is impressive, and relaxation can often be produced with but two or three minutes of ether on the Boyle machine. Once relaxation has been obtained a return is usually made to the trichlorethylene, and no further ether is required for the duration of anaesthesia. It thus appears that trichlorethylene is an excellent "maintenance agent," and its best effects are to be observed when it is used as such.

From the preceding paragraphs it becomes obvious that trichlorethylene is given no part in producing relaxation, and this is even truer when considering the minority of cases which need additional degrees of muscular relaxation. These cases

consist chiefly of abdominal operations, particularly those involving the upper abdomen, and trichlorethylene plays little part in such work. There is, however, one interesting combination which has been used a considerable number of times with complete success—viz., avertin followed by nitrous oxide and trichlorethylene, which allows of abdominal surgery with an adequate degree of relaxation. This combination offers advantages where diathermy is required inside the peritoneal cavity, but attention must be paid to the time of administration of the avertin so that the operation may start 10 minutes after the drug has been given. Lack of attention to this detail soon leads to failure.

The exact relationship between depth of anaesthesia and the degree of muscular relaxation is difficult to determine, but depth alone is not the only major factor. Probably the activity of the respiratory centre has an equally important role, and in this respect it is interesting to note that careful attention to respiration under trichlorethylene will often allow an adequate relaxation for what are sometimes difficult operation fields—e.g., herniotomy and appendicectomy. Rising respiratory rates in such cases almost invariably invoke comments on "tightness" from the surgeon.

Amount of Anaesthetic Agent Required

I have stressed the undesirability of using much trichlorethylene, and further details must now be given of the various signs which have been found helpful in judging the need for more or less anaesthetic during the course of the operation. These signs are characteristic of trichlorethylene, and close observation of any patient will show how they form a picture, some details of which are outlined also by other agents, but in which most of the finer lines are individual.

(a) Overdosage

Overdosage is considered first, for usually as indicated, our machines give too big a vapour concentration and overdosage is much easier than the reverse. The easiest sign is the rise in the respiratory rate, which may occur soon after the usual induction or at any stage during the course of the anaesthesia. The rise is often quite sudden, and with careful watching is soon detected, although the respiratory rate is usually about 35 a minute before the observer becomes aware that it is too fast. At this point there is only one course of action—removal of the source of trichlorethylene and allowing what is already in the patient to diminish gradually through loss at the expiratory valve. It is then found that the rate gradually subsides to a reasonable level, and over a period of about 5 minutes falls to 20–30 a minute, which is about the average for this agent when used carefully. When this level has been attained a minimum of trichlorethylene should be readmitted for maintenance and a very careful watch kept for a further increase of rate. This may occur a second time, but the condition is just as amenable to treatment as before (or even more so) and rarely does the trouble appear more than twice in the same subject, so the remainder of the operation is free in this respect. It should be emphasized that adequate time must be allowed for the respiratory rate to return to normal. The time varies with the degree of overdose, but usually about 5 minutes is required on the Boyle machine with a total gas flow of about 6 to 8 litres a minute. Some cases respond in a few minutes, others may need 10 to 15 minutes, but all respond in the right direction, and show a marked improvement before they become inadequately anaesthetized as of course all cases eventually will unless receiving a very high percentage of nitrous oxide. High concentrations of nitrous oxide with trichlorethylene have been found undesirable, as there is an increased tendency to tachypnoea, and the reverse is shown when high oxygen concentrations are used. The patient who is allowed to continue with a much raised respiratory rate becomes increasingly difficult to quiet, so that the condition may then persist for the remainder of the operation in spite of otherwise adequate measures. Immediate attention should always be given to this complication.

It is estimated that 90% of all cases under trichlorethylene will show this rise of respiratory rate in response to an overdose of the agent, and most of the remaining 10% experience respiratory arrest. This occurs suddenly, without any preliminary respiratory variations as may be observed with some

other agents. It responds always to a lowering of the vapour concentration, with perhaps a little help from carbon dioxide and oxygen, and of course it causes additional anxiety. Individuals who show this reaction may do so again during the course of the operation with early administrations it was once recorded five times during one operation, after which a change was made to another agent. These patients seem to jump from first or second plane straight down to respiratory arrest without any intermediate signs. The reaction has never been observed in any case showing tachypnoea.

There still remains one further small group of patients who give trouble from overdose, but of a peculiar type. Here the only observation that can be made is that the respiratory rhythm is "not quite right." On careful examination it is found that the length of each respiration varies, and particularly is this so with the expiratory fraction. Some are short and crisp others longer and slightly irregular, and yet even with these variations the type of respiration is "automatic," and the patient is of course surgically anaesthetic. These cases respond well to a removal of trichlorethylene and after a few minutes there is a return (often sudden) to the correct satisfying automatic respiration. In these cases there may also be some slight tachypnoea but this is not marked.

It must not be overlooked that a very small percentage of the cases will show no rise or other change of respiratory rate whatever even under an obvious overdose. These cases are few and far between, but their existence may help to explain the delayed recovery sometimes seen, or other peculiar complications which have been described.

(b) Underdosage: Patient becoming too "Light"

Two main signs are found to be of service here. They are the respiratory rate and the presence of stridor. As the anaesthesia lightens, the respirations, as already noted, gradually become slower and quieter, until eventually their slowness and quietness become "too flattering," when caution should be exercised. It is here that stridor often makes an appearance, followed by a period of difficult anaesthesia. The stridor may occur suddenly with great severity, but more often it is of gradual onset and the usual clinical picture is of a slow quiet respiration associated with a definite stridor which does not improve but indeed deteriorates until more anaesthetic is given. If the anaesthesia has been of short duration until this moment, then movements of the fingers and feet and sometimes face and head are also seen, but rarely do these signs give any useful information before those previously described.

It must be remembered however that respiratory rate and depth under anaesthesia depend also upon the degree and severity of the surgical stimulus, and upon individual susceptibility to these stimuli in addition to any specific pharmacological action of the anaesthetic agent in use at that time. This must be carefully borne in mind, for an inadequately anaesthetized patient will show many respiratory variations at the onset of operation, and any particularly severe stimulus (e.g., crushing of the sciatic nerve) may temporarily affect one who is otherwise adequately anaesthetized. Also it occasionally happens that in correcting a rapid respiratory rate due to trichlorethylene overdosage the patient swings quickly into the realm of inadequate anaesthesia, and the respiratory rate, which at first was diminishing satisfactorily, starts to rise again in response to an increasing stimulus. This may cause some difficulty at first, but it is soon recognized by the association of other signs, such as stridor, and perhaps muscular activity. Furthermore, if the patient is carefully watched, this state is detected before any further difficulty arises and can be treated accordingly.

Abnormal Findings under Trichlorethylene Anaesthesia

(a) Cardiac Irregularities

Irregularities occur in about 6% of all cases anaesthetized with trichlorethylene, and careful examination seems to indicate that they are extrasystoles. Unfortunately ECG findings have not been available. The clinical course of these cases is usually along the following lines. At first there is a gross irregular irregularity of pulse lasting for several minutes, which eventually gives place to a pulsus bigeminus—viz. a normal

beat, an extrasystole, and a pause—and this state usually lasts for about another 5 minutes, at the end of which time, and some 10 to 15 minutes after the onset of irregularities, there is a sudden termination of irregularities and a return to a normal regular rhythm, which then remains as such for the rest of the operation. The change to normal rhythm is often sudden, but sometimes pulsus bigeminus is replaced by trigeminus, then an extrasystole at increasing intervals, and finally a normal rhythm with an occasional extrasystole at infrequent intervals. These irregularities are usually seen at the outset of the anaesthesia, and they have always been observed to run the course outlined above, and have never caused any clinical disturbance or upset. The administration of the anaesthetic is not interrupted, and although some cases have occurred during periods of obvious overdose they cannot be associated in general with this state.

Similar abnormal cardiac rhythms are also to be observed under other anaesthetic agents, and the above picture is by no means characteristic of trichlorethylene. More careful observations may indicate that these irregularities are related not so much to the agent as to the type of induction of anaesthesia and to the physical disturbances of respiration consequent on breathing into machines and through valves, or to the presence of laryngeal spasm. However, such obvious signs must not pass unheeded, and always a careful watch should be kept for clinical features in such patients. More careful investigations—by E.C.G. studies, etc.—are obviously desirable.

(b) Nerve Palsies associated with Herpetic Lesions

Two papers were recently published in the *B.M.J.* (Carden, 1944; Humphrey and McClelland, 1944) giving details of cranial-nerve palsies together with herpetic vesicles, and the association of these conditions with closed-circuit trichlorethylene anaesthesia. A reaction between trichlorethylene and soda-lime, with the production of a toxic compound, dichloroacetylene, which is responsible for these lesions and in some instances for the death of the patient, seems a reasonable conclusion from the evidence presented. In support of this claim a similar case has been observed at this hospital. This case occurred some considerable time ago, and was among the first 100 cases anaesthetized with this drug.

A strong healthy man aged 26 came to operation a second time for internal derangement of the knee-joint. The first operation, performed under N₂O-ether, was without complications. The second was done under N₂O-trichlorethylene after premedication with omopon 1/3 gr. and scopolamine 1/150 gr. Induction was performed on the Boyle machine, and a little ether was added at the start to obtain the necessary relaxation, after which a return was made to trichlorethylene alone. Soon after induction a Waters to-and-fro absorber was introduced into the circuit, and closed-circuit anaesthesia maintained for the remainder of the operation—1 hour. It must be pointed out that this was the second case that morning which had been given closed-circuit trichlorethylene, and the same canister of soda-lime was used for both. It was noted, with the first case, that the absorber became very hot. On recovery this patient had considerably more vomiting than is usual, and there was some headache. The second case gave evidence of a bilateral trigeminal analgesia occurring 24 hours later, with an eruption of minute vesicles around the mouth after 48 hours. On the third day there was some interference with vision in the right eye, but no diplopia or loss of movement. A right facial palsy (lower motor neurone type) developed on the fifth day, and on the eleventh day the ophthalmologist reported two or three small vesicles on the epithelium of the right eye. The patient made a slow recovery, and after three months the facial palsy was cured, but there was still slight hypo-algesia of the face—"feeling of numbness."

The following details of the present condition of this patient (1 year 8 months after operation) were very kindly sent me by Dr. R. J. Isaac.

"Still complains of numbness of whole of face and tip of tongue. Some impairment of sensation of light touch over the whole of the trigeminal area (bilateral). Notices that air dust causes no pain in the right eye. Some impairment of vision in the right eye. No obvious residual 7th-nerve palsy, but slightly more difficult to close the right eye than the left. Symptoms are said to be worse in cold weather."

This case caused great interest, and it was at that time very carefully examined for any evidence which might link the aetiology with the trichlorethylene, but it was decided

that any association was unlikely. This belief was strengthened by the report from the dermatologist, and later from the neurologist, who agreed with the diagnosis of herpes zoster. It was considered, therefore, as a case of herpes zoster complicated by other cranial-nerve palsies, and of chance association with the immediate post-operative period. No further significance was given to this single case until the recent report of cases of a similar nature, when the old notes were inspected and showed the following significant facts:

1. Closed-circuit anaesthesia was used, and the soda-lime had previously been in contact with trichlorethylene, and had shown marked temperature rise.

2. Recovery was slow and vomiting considerable. Indeed, both cases which had had closed-circuit trichlorethylene anaesthesia that morning showed a slow recovery with much vomiting, and a note entered at the time states that "Sister said she thought neither of these two cases had had the 'new' anaesthetic."

Of the very large number of cases that have been anaesthetized with trichlorethylene fewer than 6 have been given closed-circuit anaesthetics. The significance of this one case, occurring as it does in so limited a number of closed-circuit anaesthetics when so many semi-open anaesthetics have been uneventful, cannot be overlooked, and, pending final proof in this matter, trichlorethylene should be rigidly avoided in all closed-circuit machines.

Delayed recovery, prolonged vomiting, marked headaches, and other abnormal findings which have been reported, have not been observed during the routine use of this anaesthetic on the Boyle, the Marrett, or similar trichlorethylene-air apparatus.

Conclusion

Trichlorethylene was first used nearly two years ago. Its distribution was then still very limited and a small supply was obtained privately. It has been employed consistently since that date, and now approximately 2,000 cases have received trichlorethylene as either the major or the minor agent, and have been personally supervised. These cases include all the types of operation commonly met with at a large general hospital, except intrathoracic surgery (excluding empyema) and extensive intracranial operations. Orthopaedic, gynaecological, midwifery, and general surgical cases comprise the bulk of this total. Ages have ranged from 3 months to 90 years, and the patients have shown all states of physical fitness.

At first some difficulty was experienced with this anaesthetic agent, as already indicated, and some of the untoward signs previously described caused confusion. It was noted, however, that these difficulties became more infrequent and less troublesome as further experience was gathered in its use. It is suggested, therefore, that many of the complications and "hazards" of trichlorethylene are not indeed such by nature, but are due to faulty administration and to misuse of a valuable agent.

To obtain the best results from trichlorethylene it is essential to know its characteristic features. It is not enough to place it in the chloroform bottle and to expect similar signs and the same response as are obtained with ether. The whole picture must be carefully understood, and the utmost emphasis must again be laid on the limitations of this agent. When it is used with the knowledge of its peculiarities and a respect for its limitations it attains a position of value which many anaesthetists now recognize.

Summary

Details are given of induction and depth of anaesthesia usually obtained under trichlorethylene anaesthesia. No attempt should be made to "push" this anaesthetic for additional depth or more muscular relaxation. It should be used only as a "maintenance agent."

Signs associated with overdose and underdose are described, together with an outline of their treatment.

Details are given of abnormal findings during and after anaesthesia.

My thanks are due to Dr. A. D. Marston and Dr. C. Langton Hewer for their kind help and advice, and to the medical superintendent, Dr. E. D. Grasby, for permission to publish the details of the above case.

TREATMENT BY MOVEMENT

BY

JAMES CYRIAX, M.D.

Assistant Medical Officer, Physiotherapy Department,
St Thomas's Hospital

The essence of the treatment of moving parts is movement. The manner in which therapeutic movement is most effectively applied varies from tissue to tissue. Choice of method is also influenced by the nature, position, and extent of the lesion, the integrity or not of such structures as nerve and bone, and the presence or absence of bacterial infection. In affections of moving parts, therefore, a necessary preliminary to treatment by movement may be the elimination of sepsis, the reduction of a fracture, splintage, or operations. The object of all these measures is to put the patient into the best position to benefit from treatment by movement. Speed is essential, for the shorter the period of immobilization the smaller the amount of stiffness and weakness.

The relative gravity of soft-tissue and bony injury must be assessed, and treatment directed to the more important component. Thus, in fracture of the surgical neck of the humerus the injury to bone can be ignored and the associated damage to soft parts treated at once. In other cases—e.g., a Colles's fracture—the paramount consideration is at first the maintenance of accurate reduction. The usual result of fracture or the shaft of the femur is not failure of the bone to unite but a stiff knee. Hence Young's (1942) method of so putting up this fracture that knee flexion exercises can be begun at once provides another instance. Again, the renewed advocacy of plating for fractures of the leg bones (Burns and Young, 1942) clearly results from a wish to facilitate treatment by immediate movement. External splintage entails a stiff tarsus and a prolonged period of rehabilitation during immobilization and after the plaster cast has been removed. Internal splintage means that such stiffness is never allowed to develop. Orthopaedic surgery is undergoing changes as a result of orientation towards measures whose cardinal aim is to keep moving parts moving from the start.

Therapeutic movement may be divided into two categories—specific and non specific. Those movements that bear directly on the patient's disability are termed specific; those that maintain general physical fitness and affect the injured part only incidentally are called non specific. Non specific movement takes the shape of gymnastics, games, and occupations like carpentry or gardening; they are performed under the supervision of the gymnast or craftsman and are not considered further in this paper, which deals with the more individual application of treatment by movement.

Specific Movements for Muscles

The chief function of muscle is to contract as it does so it becomes wider. Thus the primary requirement for muscle is a capacity to broaden fully; the secondary to lengthen fully.

Active Exercises—These restore mobility and power to muscle and maintain cortical awareness of capacity for movement. They should be graduated and purposive so as to bring both muscle and mind into action. Active exercises represent the essence of the treatment of minor muscular traumata, in which the paramount consideration is healing in the presence of enough movement to ensure a strong and supple scar. Unwanted adhesions are best prevented from forming by full broadening out of the injured muscle; hence an adequate contraction in the position of full shortening must be secured. It is also wise to ensure full elongation of the damaged muscle by voluntary contraction of its antagonist, advantage thus being taken of reflex inhibition of tone. Passive movements can stretch but cannot broaden muscles out; they have therefore no value in the treatment of minor muscular injuries. The brachialis muscle stands alone in its unsuitability for active treatment. A contraction of muscle induced by faradism has neither more nor less local value than an equal voluntary contraction. But the patient's mind is not brought to bear. Thus faradism may occasionally be employed as a useful

prelude to active movement but never as a substitute. Otherwise the patient falls into the error of supposing that his muscles should receive periodic treatment, whereas it is essential to inculcate the idea of restoration of function by his own supervised but unaided efforts. Breathing exercises, post-operative, post natal, and postural exercises, and precision exercises for neurological disease are all carried out actively.

Resisted Exercises—These strengthen muscle and enhance its tone. They are called for when an increase in muscular power is required, hence they provide the keystone of treatment in the muscular wasting that follows disuse, immobilization, operations, or arthritis. In the case of minor muscular tears, resisted exercises should be begun only when union is well advanced, for if started too soon they put excessive strain on developing fibroblasts. These rupture again and a series of relapses leading to chronic traumatic fibrositis results. Sending a patient back to heavy work shortly after minor damage to a muscle is mistaken policy, for he is apt either to hold the part stiffly (thus avoiding therapeutic movement) or to allow a series of excessive pulls on the healing breach, each leading to renewed disablement. Herein lie the seeds of one type of traumatic neurasthenia. Unsupervised use of a muscle and the proper employment of therapeutic movement may thus be seen to have little in common. It is by free active contraction that muscular mobility is maintained in most situations, resisted exercises leading to heavy work may be instituted only when a firm and supple scar has formed.

Occupational therapy stimulates patients' interest and provides them with resisted exercises of a purposive type. The mind is brought to bear, morale is raised and precision is rewarded.

Deep Massage—When the movement of a muscle is considerably restricted by the rigidity of the part which it spans, active exercises, even begun soon after an injury, may prove ineffective in maintaining mobility. Still less can they be expected to free scar tissue already formed. This state of affairs exists chiefly near the insertion of muscles into bone and in the muscles of the trunk. Thus the fibres at the iliac origins of the sacrospinalis and gluteus medius, at the scapular insertion of the vertebro scapular, at the thoracic course of the erector spinae, at the occipital attachment of the semispinalis capitis, at the costal attachment of the abdominal oblique muscles, and at any part of the intercostal muscles can seldom be kept adequately moving by exercises of any sort. The only really effective way to restore mobility, and the best way to retain it, in these special positions is by deep massage applied transversely to the affected area. By this means the masseuse separates out the muscle fibres, thus preventing interfibrillary adhesion and rupturing such adherent scars as have already formed. This passive broadening out of muscle is only a therapeutic exaggeration of its normal behaviour. At all accessible situations deep massage is more effective than active contraction in securing full mobility of muscle in cases of recent injury, in chronic cases or in the special situations enumerated above it represents the only effective method. Active exercises follow the friction; they maintain the added mobility afforded by the massage. Thus rehabilitation by graded exercises and occupational therapy is very seldom called for in muscular rheumatism. Rheumatic—like traumatic—inflammation leads to resolution with fibrosis, not to weakness or wasting. The chief symptom is pain when the muscle moves, the aim of treatment is the restoration of full painless mobility. Accurate deep massage forms the central pivot of treatment, followed by a few minutes' instruction in the maintenance of mobility by active exercises.

Assisted Exercises—These are used to elongate muscle and in cases of muscular weakness from severe arthritis or nervous disease. When a muscle needs to be lengthened the patient contracts the antagonists as powerfully as he can, meanwhile the movement is assisted by his own body-weight, by the pressure exerted through the muscles of his other limb, springs, weights acting over a pulley, or by the masseuse. When muscle power is much reduced gravity may have to be offset by the masseuse's help, immersion in brine, or slings.

Continuous Stretching—Contracture in muscle due to ischaemia, healed sepsis, or prolonged immobilization can often be partly or wholly overcome by continuous traction with weights or by pressure splintage. Once the increased range of

movement has been secured it is maintained by passive and active movements carried out several times daily. A splint should be worn to prevent recurrence, and is particularly valuable in cases complicated by peripheral nerve lesions. The fingers must not be included in splints worn merely for a nerve palsy; they stiffen quickly, and months of rehabilitation may be required to correct rigidity that need never have arisen.

Movement under Local Analgesia.—In the immediate treatment of any muscular injury the unrestricted active movement secured by local analgesia possesses great therapeutic value. Pain ceases; whereupon local inhibition of movement is abolished, a full range of active movement resulting at once. In chronic cases local infiltration is curative only when a muscle is affected some distance from its attachment to the bone. Hydraulic pressure seems ineffective in freeing adhesions within a muscle unless the lesion lies at its most distensible part—the belly. The bellies of the trapezius, latissimus dorsi, pectoralis major, extensores carpi radialis, gluteus medius, and gastrocnemius muscles may be singled out as usually responding well to local infiltration. My view is that the action of such injections is unrelated to the local analgesic that the solution contains: the benefit is due to the physical effect—akin to that provided by natural movement or deep transverse massage—i.e., the water broadening the muscle out. Acute lumbago provides the most spectacular success for local analgesia. The patient, immobilized in bed and aware from past experience that he will remain so for perhaps a fortnight, gets up after his muscles have been anaesthetized and moves freely. Next day, apart from some soreness, he is able to go about his business. This result cannot be attained by mobilization under general anaesthesia; for this succeeds only in stretching the muscle without broadening it out. Doubtless faradism under general anaesthesia would succeed, but it is far simpler to make the patient move the muscle himself during the period of local analgesia. In severe cases the whole lumbar extent of both sacrospinalis muscles must be infiltrated to achieve this satisfactory result.

Specific Movements for Joints

Contrary to general belief, mobility is maintained at a joint just as well by passive as by active movement. It is the muscles about a joint, not the joint itself, that are influenced by the type of the movement. Hence, provided that the joint is moved, the agency is immaterial. It is difficult to see how any controversy could exist over this obvious truism. A joint is merely a passive hinge, dependent for its maintenance as such on being periodically moved.

Active Movements.—These are employed to retain mobility at a joint and slowly to increase the range. Their cardinal use is to keep normal structures normal. Thus all the joints of an injured part not actually immobilized should be put through their full range of movement daily, preferably actively, and therapeutic occupations chosen that bring the limb into effective play. The treatment after orthopaedic operations and the reduction of most fractures entails the regular performance of a series of suitably graded exercises. In most of these cases passive movements do not hasten recovery. After interference with joints such as excision of a meniscus from the knee, the traumatic arthritis set up by the operation recovers at a fixed maximum rate that is attained only when the proper exercises—first without, later with, weight-bearing—are conscientiously carried out. Inadequate treatment slows recovery and may even prevent it altogether, but there is an intensity of treatment by movement beyond which it is pointless to go.

Gentle Passive Movements.—These are used to increase the range of movement at a joint the site of a recent sprain (except the elbow). They are also required to maintain range pending recovery from neurological lesions. Adhesions about a joint are prevented from forming by the fact that the joint is moved, no matter by what agency. A ligament, for example, moves over subjacent bone just as much during passive as during equal active movement. Moreover, the patient is most quickly induced actively to increase the range of movement at a joint by a previous demonstration of the painlessness of the passive range. Full recovery from articular sprains is thus retarded by the present-day insistence on active movements alone in rehabilitation. However much this limitation may

apply to some muscles, active movements have no virtue in passive movements in the treatment of many sprains affecting joints. Indeed, they may be less effective, in so far as they are often performed through a smaller range. Hence the use of passive movements followed by their active repetition achieves the quickest results.

Forced Movements.—These are of two types—a quick and a slow stretch. A quick jerk is called for when limitation of movement at a joint is caused by post-traumatic adhesions. Patients should not be asked to rupture their own adhesions. These should be broken passively with or without anaesthesia (according to circumstances) by the surgeon or the masseur. Thereupon the patient must maintain the added range by constantly repeated active endeavours, supervised, and if necessary assisted, by the masseuse. Slow stretching out is indicated in capsular contracture due to immobilization, diffuse scarification or osteo-arthritis. Continued pressure by the masseuse or means of apparatus is required; thereupon the increased movement is retained actively. Resisted exercises for coincident muscular wasting are always called for. Movements especially forced, are contraindicated in the treatment of the joints that rely for their stability on their capsule and ligaments alone. When no muscle controls movement at a joint, sprains may result in permanent laxity. Only harm could result from further overstretching. Moreover, this is not required; for a prerequisite to adhesion formation—namely, healing in the absence of enough movement—is necessarily absent. The treatment of sprains of the acromio-clavicular, sterno-clavicular, sacro-iliac, and cruciate ligaments is protection and modification.

Deep Massage.—There exist various ligaments whose mobility is maintained or restored more effectively by massage than by any other way. The outstanding examples are the supraspinous ligaments and those at the knee. Exercises aggravate lesions of the supraspinous ligaments; mobilization under anaesthesia has little effect; whereas adequate digital friction is regularly successful in restoring mobility within a few weeks even in the most chronic cases that have resisted every other treatment. The coronary ligaments at the knee do not span the joint. Hence, adequate mobility after a sprain cannot be retained by moving the knee, whether actively or passively. Rotational sprains therefore get well very slowly. Nothing is easier than to keep the ligament moving by drawing the finger to and fro across it; and it is only by the masseuse's friction that adequate treatment by movement can be secured. Active exercises are an instruction in gait follow. Any surgeon who cares to order this treatment will find that full recovery is obtained in many weeks as it formerly took months. The same considerations apply with almost equal force to lesions of the medial collateral ligament—the commonest sprain at the knee. This ligament has a range of movement over the bones, lying anteriorly when the knee is fully extended and being drawn posteriorly as the knee is increasingly flexed. Since synovitis prevents a full range from being attained at the knee immediately, the ligament cannot be put through its full extent of movement by merely moving the knee. Hence unwanted adhesions form. Friction to the ligament moves it passively to and fro in imitation of its normal behaviour and prevents adhesion formation. Active exercises and instruction in gait follow at once. The same happens in cases of chronic sprain here: friction applied to the site of scarring wears down fibrous tissue to such an extent that passive forcing without anaesthesia becomes easy. In this case the massage prepares the way for the mobilization. The speed of recovery from sprains of the tarsal and carpal joints is also enhanced by deep massage, but the results are less spectacular.

Resisted Exercises.—These are employed when a diminished range of movement at a joint is desirable. A joint may be so disorganized that all movement is painful, and the patient too elderly for an operation like arthrodesis. This is often the position in advanced osteo-arthritis of the hip. An attempt to stabilize the joint by increasing the strength and tone of the muscles about it may be made by the use of faradism, static contractions, or exercises so resisted that no movement takes place. Exercises are given for the same reason to the short flexor muscles of the foot in the treatment of strain of the mid-tarsal joint or plantar fascia. The increased strength

of these muscles diminishes movement, thus avoiding excessive stress on the joint capsule or fascia. Compensation for over-stretching of the cruciate ligaments, by increasing the strength and tone of the quadriceps muscle, provides another case in point.

Specific Movements for Tendons

Tendons are treated only passively. Since tenosynovitis and tendinitis are often the result of over-use, exercises merely repeat the causative strains and aggravate the condition.

Deep Massage.—In tenosynovitis, the cause of the pain appears to be friction between the surface of the tendon and the inner aspect of its sheath. The phenomenon of crepitus shows that roughening of these surfaces occurs, and the fact that cure follows operations slitting the sheath up shows that the roughening ceases to matter as soon as the sheath no longer fits accurately. Orthodox treatment by immobilization is cumbersome, slow, and uncertain in its results; moreover, in some situations (e.g., at the knee or shoulder) it is barely feasible. Deep massage to the affected stretch of tendon is always the treatment of choice, and is quickly successful. At the wrist, shoulder, and knee failure is almost unknown. In the case of tenosynovitis, it is my belief that the masseuse's transverse friction smooths the roughened surfaces off again. Though the results in tendinitis are equally consistent, the mode of action is obscure.

Manipulation.—A minor tear at a teno-periosteal junction can sometimes be stretched out enough to allow healing with slight lengthening. Mills's manipulation for a tennis-elbow acts in this way.

Anaesthesia and Analgesia

These are required when an attempt at the projected movement sets up such pain that the patient cannot allow its performance. Four methods exist, each with its own indication.

General Anaesthesia.—Consciousness has often to be abolished when the spinal, shoulder, knee, and tarsal joints require mobilization. Full muscular relaxation is an essential preliminary to forcing movement.

Local Analgesia.—Stretching muscles out under general anaesthesia has little or no therapeutic value, since broadening of the muscles cannot be secured thus. On the other hand, active use during the period of local analgesia, by allowing full broadening during a contraction that pain would otherwise have prevented, is a most useful measure, particularly in acute lumbago and minor muscular tears. Local analgesia is also the treatment of choice in ligamentous sprains during the first 24 hours after the accident. Not only is movement facilitated but the reflex that causes oedema, effusion into the joint, and muscular spasm has its point of departure removed for the duration of analgesia. Division of muscular or fascial adhesions with a tenotomy knife under local analgesia, followed by immediate active movements designed to ensure healing with lengthening, is called for in stubborn lesions of the trunk muscles.

Heat Analgesia.—Heat increases blood supply and thus enhances the speed of destruction of the substance—Lewis's P-factor—responsible for the pain. Heat applied to a structure before it is stretched enables the patient to permit forcing through a greater range. To this end, the heat must reach the tissue at fault, usually the capsule of the shoulder, hip, or spinal joints. Hence short-wave diathermy is required; radiant heat has far too superficial an effect.

Massage Analgesia.—When a soft structure accessible to the masseuse's finger is to be treated by movement, deep massage is usually called for and has two effects. It induces traumatic hyperaemia; hence relief from pain is felt as soon as the friction ends. Like heat, therefore, massage given deeply results in an enhanced oxygenation of P-factor. Unlike heat, it also applies therapeutic movement to the part. Friction should thus be preferred for its double action when accessible structures need to be moved, heat being reserved for those outside the masseuse's reach.

Rehabilitation

The best rehabilitation is such effective treatment in the first place that little is required. When overriding considerations—e.g., sepsis, more serious injury elsewhere, or environmental lack of facilities—lead to the development of stiffness and

weakness, much time and endeavour must be devoted to the restoration of function. The present trend of orthopaedic surgery is towards the adoption of measures which ensure that treatment by movement can be begun so soon after the injury that stiffness and weakness have not had time to develop. In such cases active exercises maintain rather than restore power and mobility.

Graded exercises form an important part of the technique of rehabilitation. But it is a retrograde step to limit the scope of rehabilitation to active exercises alone. The particular method should be chosen that best brings treatment by movement to bear on the affected part.

Masseuses' main function is the application of treatment by movement. They are skilled in its three main divisions—active movement, passive movement, and deep massage. It is mistaken policy to limit treatment to the use of only one of these three measures. The indications for each kind of therapeutic movement are distinct but by no means mutually exclusive. Though it is undeniable that until lately there existed a tendency for masseuses to administer much misdirected radiant heat and gentle massage for conditions calling for exercises or deep massage, the pendulum is now swinging too far the other way. At present patients whom properly given friction would quickly relieve stand in real danger of being set to perform a series of exercises. Hence a sense of proportion must be maintained and the whole field of treatment by movement surveyed before the appropriate method is chosen and the masseuse instructed.

There is only one difficulty. A decision on the type of treatment best calculated to restore mobility rests on an accurate determination of the site of the lesion and of the nature of the damaged tissue. Deep massage affords effective treatment by movement only when applied to the right spot in the right way. Hence the masseuse must be provided with a diagnosis precise in detail before any question of friction can arise at all. The same applies to local analgesia, whether employed for diagnostic or for therapeutic purposes. Clearly, at a rehabilitation centre or in a physiotherapy department no less than in the other parts of a hospital, the best results are obtained when an exact diagnosis affords the pointer to equally exact treatment.

Summary of Principles

Most of the muscles of the limbs can be kept strong and mobile by active, later resisted, movements.

The muscles of the trunk span rigid parts and thus require deep massage to restore their mobility; active exercises then retain the added movement. This applies as much to traumatic as to rheumatic fibrosis.

Acute fibromyositis, whether traumatic or rheumatic, is best treated in the first instance by active movement under local analgesia.

Joints under muscular control (except the elbow) should be treated by movement after a sprain. Whether such movement is passive or active is immaterial; in practice, passive followed by active movements secure the best results.

Joints not under muscular control should be treated by rest after a sprain.

A few ligaments are more effectively moved by deep massage than in any other way. Active exercises retain the added range. During the first 24 hours after a ligamentous sprain local analgesia is the treatment of choice.

Tendons are treated by deep massage. No exercises follow.

Rehabilitation entails the selection of the type of therapeutic movement best suited to the lesion present, after precise diagnosis has been arrived at.

Full use should be made of masseuses, whose main function is the application of treatment by movement.

G. H. Faget and others (*Publ. Hlth. Repts. Wash.*, 1943, 58, 1729) have tried out a number of sulphonamide drugs in the treatment of leprosy. They find that the most effective of these is promin (known as promanide in Great Britain). They do not claim that it is a specific of leprosy, and observe that it has no bacteriostatic action on *M. leprae*, but conclude that it is capable of inhibiting the progress of the disease in a number of cases, the drug for the most part being given intravenously.

A FATAL CASE OF MUSTARD GAS POISONING

BY

F. BEDO HOBBS, M.D., M.R.C.P., D.P.H.

Medical Superintendent, Farnham County Hospital

There have fortunately been no opportunities of seeing the fatal effects of mustard gas on human beings in this country since the last war; therefore it may be of interest to record my observations on a family who became contaminated with mustard gas, and the post-mortem findings on the one patient who died.

History of Case

Some boys entered a W.D. area and found a few mustard bombs which had exploded and been left covered with bleach powder. They threw stones at them, and one burst into flames, giving off smoke to which a boy aged 8 was exposed for several minutes. Later, when the flames were extinguished, he picked up the bomb and in so doing scattered some of the contents on his jersey and trousers. This was a white powder consisting of bleach mixed with the remains of the liquid mustard in the bomb. The boy returned home about an hour later complaining that his arms and legs were burning. His mother states that the exposed parts of his body, not face, looked as if they were severely sunburnt. She stripped and washed him and put him to bed. She washed his jersey, but the other clothing was left hanging in the room where the mother and four children were sitting for an hour or so before going to bed.

About two hours later the boy started vomiting, as did the other members of the family, and all complained of intense pain and irritation of the eyes. By the next morning five members of the family were suffering from severe conjunctivitis, and the boy had blisters on his penis and thighs, while his elder brother, who shared a bed with him, also had blisters on his thigh and arm.

Clinical Record and Treatment

The mother and four children were immediately admitted to hospital. The originally contaminated patient was suffering intense discomfort from his eyes; they were watering profusely, and he was quite unable to open them. The penis was swollen and blistered, as were the inner parts of the thighs, while an area of erythema extended over the forearms, abdomen, and thighs. The blisters were aspirated and cod-liver oil applied to the burnt areas. The eyes were irrigated with normal saline every two hours, 10% sulphacetamide (albacid) drops were instilled every four hours, and 1% atropine drops were put in twice a day until full dilatation was obtained.

During the next 24 hours further blisters developed, spreading peripherally from the original burns and also on the buttocks, which rapidly became very raw. Vomiting ceased, but was replaced by an irritable cough. The respirations rose to 40 a minute, the temperature to 101.2°, and pulse to 140; the boy was restless and delirious, and incontinent of urine and faeces. This stage continued for about 36 hours, with alternating periods of lucidity and delirium. He began to show signs of pulmonary congestion, and was given sulphathiazole tablets. Frequent irrigation of the eyes was discontinued 24 hours after admission, and the exudate merely washed out before putting in the sulphacetamide and atropine drops.

Three days after admission his general condition improved; he was rational and no longer incontinent, and took his food and drinks well. There was slight oedema of the cornea, and the conjunctivitis was still very marked, though he was now able to open his eyes.

The burnt areas, chiefly of first and second degrees, were clean, but the erythematous areas on the legs, arms, abdomen, and chest were gradually extending and being replaced by blisters. The cough was very troublesome at times, chiefly tracheal in type, and a few crepitations were heard at the lung bases. There was some nasal catarrh but no sputum. Inhalations of menthol compound on a Burney Yeo mask gave some relief. The temperature all this time was fluctuating between 98 and 101°, but the general condition was improving, and sulphathiazole was discontinued on the sixth day after admission, 23 g. having been given. At this stage his non-protein nitrogen and urinary calcium were normal, and a sternal puncture showed no abnormal cells.

A blood count taken on the fifth day showed 13,000 white cells per c.mm. with 88% polymorphs, but two days later this had dropped to 3,800, when the sulphathiazole was discontinued. From this date the white cell count and also the haemoglobin fell rapidly and the temperature steadily rose. The boy became very irritable and particularly resented exposure of his skin to the air. The pulmonary signs increased and he appeared to have difficulty in clearing mucus from his trachea.

His abdomen became very distended and tender, especially the right side. His white cell count on successive days was 13,760, 3,800, 1,200, 600, 200 per c.mm., and at this stage the cells were made up of polymorphs 12%, monocytes 14%, lymphocytes 26%, pathological lymphocytes 48%. Blood transfusion been considered when the agranulocytosis developed, but was done as it meant cutting down through burnt tissue. However four or five injections of 10 c.cm. of pentnucleotide had no effect it was decided to start continuous blood transfusion, and between the eighth and tenth days three pints of fresh blood and one of glucose-saline were given. On the eleventh day his abdomen less distended and tender and the bowels were acting. The temperature was, however, 104°, respirations 30, and the cough was troublesome. Mentally he was bright, he was drinking well, his kidneys were acting normally. His condition, however, steadily deteriorated during the next 24 hours, with increasing difficulty in respiration, and he died at 2 a.m. on the twelfth day after the accident.

Remainder of Family

The mother and three other children were suffering from acute conjunctivitis on admission. They all responded well to treatment with sulphacetamide and atropine, and their eyes were almost normal within a week.

One of the boys who had shared the patient's bed had blisters on the thigh and forearm, and during the next week these extended his penis became blistered, and a well-marked erythema developed on the bathing-drawers area. A very troublesome cough started on the fourth day but soon cleared up. On the sixth day he vomited and complained of abdominal pain, about the same time that his brother also had acute pain due to a duodenal ulcer. The pain in this case, however, subsided in about 24 hours. Another boy, who also shared the bed, had acute conjunctivitis and developed blisters on the buttock and perineum that, although remaining clean, took eight weeks to heal.

Three other members of the family—girls aged 5 and 12 and boy aged 2—were admitted about a week later with severe cough and the two youngest developed a bronchopneumonic condition. These were in bed when the contaminated boy came home, and presumably were affected by vapour from the clothes the following morning.

Several members of the family showed a definite reduction in the white cell counts, which were taken on the tenth day. The majority were from 4,000 to 6,000 per c.mm., though one boy had a count as low as 2,800. In the course of a week all these counts increased by 2,000 or 3,000, coincidentally with an improvement in the general condition.

Post-mortem Examination (Dr. Eric Gardner)

A well-built boy with extensive first-, second-, and third-degree burns on the body, some healed and the remainder healing satisfactorily.

Brain: 55 oz.—rather severe congestion superficially and on section. Pharynx congested. Membranous ulceration of larynx and membranous tracheitis and bronchitis, seen also in section of lung in larger bronchi with some peribronchial consolidation. Right lung: Lower lobe—massive collapse superficially, centre of lung aerated; upper lobe—similar to a less extent; solid oedema of lower lobe. Left lung: Similar condition of collapse but less extensive. Heart: Vessels, valves, and myocardium normal to naked eye. Stomach: Mucous membrane congested. Duodenum: Ulcer 1 cm. in length; ulcerated completely through mucous membrane on to muscular coat. Jejunum and ileum: Mucous membrane congested; fading out in ileum. Caecum: Area of ulceration finger-print sized. Colon: Slight congestion. Liver: 36 oz.—smooth; terminally congested. On section, pattern blurred and surface glazed (cloudy swelling). Spleen: 4 oz.—swollen; firm and deeply congested. Kidneys: 8 oz.—deeply congested; surface veins prominent; capsulae adherent in patches. Cortex—radial lines of congestion; pelvis congested and oedematous. Patches of congestion in ureters. Adrenal glands oedematous; bladder normal. Section of tibia: Red bone marrow pale; considerable pallor in head and upper end of shaft. Vertebrae, deep brownish colour on section.

Summary.—A membranous ulcerative laryngitis and a membranous ulceration of the main air tubes of the lung had led to a massive collapse of that organ—the immediate cause of death. Further changes were noted in the glands of the body and in the bone marrow, consistent with and consequent upon the changes in the blood. The cause of death was: (a) agranulocytosis; (b) multiple burns from mustard gas.

Summary of Microscopical Examination of Tissues (Prof. G. R. Cameron)

Severe pulmonary oedema and haemorrhage, with macrophages, infiltration, acute desquamative bronchitis and bronchiolitis, slight peribronchitis—no bronchopneumonia; acute desquamative tracheitis with false-membrane formation; acute ulcerative laryngitis with false-membrane formation; acute ulceration of first part of

nodum; cloudy swelling, congestion, cast formation in kidneys; cloudy swelling and early necrosis in liver; distension of spleen with red corpuscles; depletion of lymphoid tissue in spleen, mesenteric, inguinal, and pre-aortic lymph glands, with lymphoblastic proliferation; disappearance of granular polymorphonuclear leucocytes and myelocytes from bone marrow.

Comments

The outstanding features in this case are:

1. Terminal pulmonary oedema and haemorrhage, both of which appear to have developed within the last one or, possibly, two days of life, judged by the relatively slight cellular reaction in the lungs.
2. Acute bronchitis and bronchiolitis, which must be grouped with the laryngitis and tracheitis, since all show the same degree of inflammatory change and epithelial damage. These changes are of minor standing than the pulmonary oedema and haemorrhage, and are to be attributed to inhalation of mustard vapour.
3. Ulceration of the duodenum (and of the caecum) of some days' duration—probably at least a week; it is certainly not terminal.
4. Depletion of lymphocytes, with lymphoblastic proliferation, suggests a longer process—i.e., is not terminal.
5. Haemorrhages in the adrenals.

The mild degenerative changes and slight necrosis of liver and kidneys are difficult to separate from post-mortem change—a source of error which has to be seriously considered here, since the necropsy was delayed for about 30 hours. However, the presence of granular and "calcium" casts in the kidneys is evidence of some damage to these organs during life. These changes do not, however, suggest sulphathiazole poisoning if the findings described in monkeys with this drug (Climenko and Wright. *Arch. Path.*, 1941, 32, 794) are applicable to man.

Discussion

In the boy's case the contamination was due partly to mustard vapour and partly to a mixture of liquid mustard and bleach powder. The contamination of the family was due to vapour given off from the boy's clothing, which was hanging in the living-room.

In the war of 1914-18 it was found that the majority of mustard gas casualties were due to vapour. These were caused not by inhaling the gas directly on the field of battle, but by a contaminated man going into a billet or dug-out, whereupon the liquid contamination on his clothing evaporated, resulting in a high concentration of vapour in a confined space, which caused many casualties indirectly among hitherto unaffected and uncontaminated men. This is well illustrated in the present case, for one individual was contaminated by liquid and seven others became vapour casualties indirectly. The obvious warning is, *Never take contaminated clothing into confined space.*

Initial Symptoms.—Apart from the burning sensation of the skin in the contaminated boy, vomiting was the first symptom in all the patients. This is now well recognized clinically in mustard gas poisoning, and is followed a few hours later by irritation of the conjunctiva.

Burns.—The burns were chiefly of the first and second degrees. It does not seem to matter greatly what treatment is used for these, so long as attention is paid to strict asepsis, according to those who have had most experience, acriflavine solution, liquid paraffin, tulle gras, etc., will all give satisfactory results, and it is suggested that the treatment which is most readily available and understood by the nursing staff should be used. It is important to aspirate the blister fluid under aseptic precautions in the early stages, and to preserve as much of the blistered skin as possible. In this connexion methyl salicylate limits the effusion, but is expensive, is not always readily available, and is irritating to the scrotum and face; in the whole, therefore, it is not applicable to large numbers of cases. Fomentations should not be used, nor should tannic acid, as recent work has shown that when a large area of burnt skin is tanned there is a possibility of absorption of urmic acid, giving rise to liver-cell necrosis (personal communication from Prof. Cameron). That fresh patches of erythema and blisters continue to develop for seven to ten days is a well-established clinical fact, and is not, as is sometimes thought, due to reinfection. Healing of the burnt area

is often very slow. One of the boys with a second-degree burn about 3 in. by 2 in. on the perineum took eight weeks to heal, although there was no secondary infection.

Eyes.—Miss Ida Mann, in a personal communication from the Nuffield Laboratory of Ophthalmology, classifies the clinical signs of mustard gas burns of the eyes into four grades as follows:

Group 1. Very Mild.—Lids and sometimes conjunctiva red, cornea clear. Sometimes slight oedema of the lids and lacrimation. No photophobia. No treatment required.

Group 2. Mild.—In addition to the above there is superficial corneal haze, lacrimation and/or discharge (profuse), photophobia and/or blepharospasm. Treatment consists in keeping the eye clean, using mydratics and only non-irritating antiseptics. Do not bandage the eye; reassure the patient, as there is a large element of fear. Recovery should take place in one to three weeks, and is complete.

Group 3. Severe.—In addition to the above there is deep corneal haze—(a) without new vessel formation, (b) with new vessel formation. Treatment is on the same lines as with Group 2. The case takes several weeks to recover, and if Group 3 (b) there may be relapses and prolonged disability, with final recovery.

Group 4. Very Severe.—As above, but with iritis, copious and prolonged discharge, and inability to open the eyes for a period of weeks or months. Partial recovery follows in about nine months. There is a risk of ulceration following prolonged degenerative processes, occurring after five to ten years. Treatment is by mydratics, cleanliness, and non-irritating antiseptics.

The present case would appear to fall into Group 2 or Group 3 (a). Discharge was not a feature and there was not much corneal haze. In all cases intensive irrigation is irritating and harmful. A non-irritating antiseptic would seem to be indicated when secondary infection is present. Mydratics relieve the pain and spasm.

Trachea and Lungs.—Tracheitis is an early symptom, and should be relieved by inhalations. An irritable cough starts on the second to fourth day, and bronchitis or pulmonary oedema develops, or the condition gradually subsides in a few days. The usual remedies are applicable here.

Blood.—The obvious question of the cause of the agranulocytosis was whether it was due to the sulphathiazole, of which the patient had received 23 g., or whether it was due to the mustard gas. I understand from Prof. Cameron that this condition was recognized in the last war as an occasional sequela of mustard gas poisoning and that much experimental work has confirmed its importance. The post-mortem findings did not suggest that the agranulocytosis was due to the sulphathiazole, and the fact that some of the other cases which had no sulphonamide also showed a marked diminution in their white cell counts eight to fourteen days after the contamination strongly suggests that the mustard gas was the causative agent. The question naturally arises whether sulphonamides should be used in dealing with mustard gas cases, and investigation of this problem is urgently required. It is known that mustard has an affinity for lymphoid tissue, and the relatively greater proportion of this tissue in children may make them especially susceptible.

Intestinal Ulceration.—Ulcers of the duodenum are well known as a textbook complication of burns, although I believe they must be relatively uncommon. This is probably due to the fact that patients often die before the ulcer has time to develop. The symptoms of pain and tenderness on the right side of the abdomen with general distension were obviously due to the ulcer found after death. A similar ulcer was present in the caecum. Haemorrhage and acute ulceration of the mucosa are, however, commonly found in experimental mustard gas poisoning.

Convalescence.—Convalescence tends to be prolonged, and good nourishing food, with extra milk and especially an excess of vitamin C, is important. The vitamin C should be given in large doses of 500 mg. 12-hourly for three doses, followed by 50 mg. twice a day, proportionately less being required for a child.

I was fortunate in being able to call upon the expert knowledge of Capt. K. Hill, R.A.M.C., in treating these cases, and to have the opportunity also of discussing them with Prof. G. R. Cameron and Surg. Lieut.-Cmdr. G. Foss, R.N.V.R. My thanks are due to all of them for their expert assistance, to Miss Ida Mann for her classification of eye cases, and also to Dr. E. Gardner for his post-mortem report.

HEPARIN IN INTRAVENOUS INFUSIONS, INCLUDING PENICILLIN THERAPY

BY

PETER MARTIN, F.R.C.S.Ed.

Surg. Lieut., Cmdr., R.N.V.R.; Surgeon, Chelmsford and Essex Hospital

The general, if not the only, anticoagulant used in blood transfusions in this country and in the United States is sodium citrate (0.3 g. per 100 c.cm. of blood). It has proved very satisfactory. It is cheap, and has, it is believed, no deleterious effects. It is not here proposed that heparin should be substituted for sodium citrate, as has been advocated by Hedenius (1937), who administered enough intravenous heparin to give the donor's blood a coagulation time of about 30 minutes: he has used this method hundreds of times with complete success. Rather it is suggested that a very small amount of heparin be employed in addition to the citrate added to blood, or to an infusion of crystalloid solution if this is preferred.

Although there is no essential difficulty in administering either a transfusion of blood (fresh or stored), plasma, serum, or an infusion of crystalloid solution, it sometimes happens that the infused substance fails to run smoothly through the apparatus long enough to give the amount intended. This is generally due either to spasm or to a thrombosis of the recipient's vein. Spasm is seen particularly after dissection of the internal saphenous vein at the ankle, and can be relieved by placing hot-water bottles along the course of the vein; it is then often surprising how, in a few moments, the blood or solution will begin to run freely. We have all met with the patient who has had several transfusions and who, again requiring one, presents no suitable vein that has not been "used" and thrombosed. It is important that a vein should not be obliterated by a transfusion, and it should be possible to use the same vein an indefinite number of times. It generally is; it sometimes is not.

Why is it that sometimes everything works smoothly and there is no residual thrombosis, and at other times thrombosis occurs and the flow stops? The condition is generally due to a thrombotic process starting, presumably, at the site of venepuncture, or to an irritating solution being infused, such as is unfortunately common in intravenous penicillin therapy.

Prevention of Thrombosis

To counteract the incidence of thrombosis in the recipient's vein it is suggested that heparin, in an amount equivalent to 1 Toronto unit per c.cm., be added to the fluid to be introduced. G. Murray (1940) reported on the use of continuous intravenous heparin in over 400 cases without a single case of thrombosis at the site of venepuncture, even though in some instances the needle was left *in situ* for two weeks and though, as he was deliberately prolonging the coagulation time of the recipient's blood, he was using a concentration considerably greater than that suggested here. It may be argued that in a transfusion on account of haemorrhage, or in a transfusion being given during or immediately after an operation, the coagulation time of the recipient's blood is liable to be prolonged. Hedenius has shown that there is a threshold for heparin in the blood below which no alteration in the coagulation time is apparent. This threshold is 0.25 mg. per kilogramme of body weight. In a patient of 8 st. this would amount to 14 mg. of heparin, and in a patient of 10 st. to between 17 and 18 mg. Now, 1 Toronto unit of heparin contains 0.01 mg. of the substance; therefore a litre of blood or crystalloid solution heparinized with 1 unit per c.cm. would contain 10 mg. It will be seen that to reach the threshold it would be necessary to infuse $1\frac{1}{2}$ litres in an 8-st. patient. As the amount of heparin contained in this $1\frac{1}{2}$ litres is destroyed hourly by the body, and as it is very improbable that there would ever be an indication to carry on an infusion at the rate of $1\frac{1}{2}$ litres an hour, it is concluded that the threshold is not reached, and therefore that the coagulation time of the recipient is not affected. This is borne out by the observation made in a few cases.

It might be said that there may be toxic effects of the heparin *per se* and that harm may result. Experimentally, Howell and Murray have been unable to show any change

in the red and white counts or in the platelets, even where the animal's blood has been rendered incoagulable; and G. D. W. Murray (1940) has given to patients as much as 600,000 units over a period of 40 days without ill effect. Nor have anaphylactic phenomena been encountered where heparinization has been repeated.

We have recently used heparin in all infusions of blood (fresh or stored), plasma, and solutions of crystalloids. The heparin is added to the infusing fluid by injecting it through the cork of the bottle by means of a hypodermic syringe. The amount used has been 1 unit per c.cm. of fluid—equivalent to 1 c.cm. of heparin B.D.H. per litre. The infusion is then carried on in the usual way. We have not had to dissect a vein in this series, and this step should only very rarely be necessary.

Between 50 and 60 cases have received heparinized intravenous therapy, and most varieties of shock, haemorrhage, prolonged sepsis, and anaemic states have been included in this series. There has been no tendency to a recurrence of haemorrhage, and in post-operative cases we have seen no evidence of bruising or haemorrhage in the area of the operation scar. In 8 cases the coagulation time was estimated before infusion and immediately afterwards. In no case was there any significant alteration, the maximum rise in coagulation time being 30 seconds and the maximum fall in value 20 seconds, these variations in the value clearly being within the limits of the margins of error of the test. There has been no evidence of toxic or deleterious effects as a result of the heparin.

Use of Heparin with Penicillin

It is suggested that heparin should be of value in preventing the thrombosis and phlebitis which are frequently seen when penicillin is given by intravenous drip. Penicillin, or at least the impure solution of penicillin available at present, irritates the endothelium of veins, causing a chemical phlebitis and a subsequent thrombosis. However, G. D. W. Murray (1940) has found experimentally that the incidence of phlebitis and thrombosis caused by the intravenous injection of sodium ricinoleate—a powerful intravenous irritant—can be reduced from 90% in controls to less than 20% in heparinized animals. According to Surg. Cmdr. C. A. Green (personal communication), penicillin is not destroyed or affected by heparin. We have in several cases employed heparin with penicillin to try to prevent thrombosis or thrombophlebitis. At first we used 1 unit of heparin per c.cm. of penicillin solution, and in five cases the full amount of penicillin was given without thrombosis, but in one the drip blocked after four and a half days. In a second batch of penicillin 1 unit of heparin per c.cm. did not suffice to prevent thrombosis, so 3 units per c.cm. were used. With this dosage it has been possible to give the required amount of penicillin without accident, at the rate of penicillin drip which we are using—i.e., 35 drops a minute—it would not seem possible to administer enough heparin to affect the clotting time.

Conclusion

Apart from difficulty with the penicillin cases, infusion has been conducted with noticeable ease in every case except one. This patient was receiving fresh heparinized blood for a secondary anaemia and toxic state following prolonged suppuration. In this instance the needle was not inserted fairly into the vein and there was leakage into the perivascular tissues. After the needle was inserted into the other arm all went well and an infusion of 4 pints of blood was successfully concluded. The original vein did not thrombose.

In no case has thrombosis of the recipient vein been seen, nor has there been any bruising of the tissues around the site of puncture. Objection to the use of heparin in infusions has been raised on the question of cost. At present heparin B.D.H. costs 8s. 6d. for 5 c.cm., which contains 5,000 units of heparin; to heparinize effectively 5 litres of blood, plasma, or other fluid, a cost of approximately 1s. 8d. per litre cannot, therefore, be regarded as excessive when the advantages of the method are considered.

Medical Memoranda

Solitary Neurofibroma in the Stomach

In the stomach, and generally in the digestive system, benign tumours, especially neurofibromata, are seldom seen. These tumours always take their origin from the gastric plexus and grow between the two layers of muscle below the mucosa. According to Askanazy, the nerve tissue seen within the tumour is sympathetic. Usually such tumours are associated with a diffuse neurofibromatosis of the skin. Leriche, and Gerhardt and Westphal, have reported numerous neurofibromata of the alimentary tract in patients with typical von Recklinghausen's disease. Kohitz described an intestinal neurofibroma in a patient with no other signs of neurofibromatosis, and Askanazy writes of a case in which the stomach and small intestine contained as many as 15 neurofibromata, the largest being the size of a walnut. Despite a search of the available literature, I have not found a previous report of an isolated neurofibroma of the stomach. The following case, in which the tumour was larger than any gastric or intestinal neurofibroma hitherto recorded, may therefore be of interest.

CASE HISTORY

On July 2, 1943, a woman aged about 50 was admitted to hospital in a very weak condition. She complained of nausea and occasional vomiting. According to her story, she was taken ill suddenly, a year previously, with violent abdominal pains, and ever since that time had suffered from prolonged, but not severe, abdominal pain with a sensation of gastric distension.

On examination the belly was soft and not resistant. A hard mobile tumour the size of a fist was felt in the centre of the epigastrium. The tumour moved with respiration. On x-ray examination a fairly regular filling defect was seen towards the middle of the stomach. Radiographs showed a large, irregular, and somewhat rough shadow. Nothing unusual was noticed in the intestinal canal. A provisional diagnosis of pedunculated tumour or a phytobezoar was made, and it was decided to operate.

On July 10 laparotomy was performed under local analgesia, and at the middle of the lesser curvature a smooth round tumour about 3 in. in diameter, covered with mucous membrane and attached by a short broad pedicle, was seen. The tumour was resected, and the wound healed by first intention. The patient speedily recovered strength and was soon herself again. On July 30, 1943, she returned to her home.

Pathological Examination (Prof. Oberdorfer, Cancer Institute of the University of Istanbul).—A round solid tumour, the size of an apple, weight 200 g, covered on all sides by mucous membrane and with a small broad pedicle, which had no mucosal covering. On section the tumour was seen to be of whitish medullary tissue, clearly distinct from the mucosa. Histological examination showed that the mucous membrane of the tumour was partly atrophied and partly degenerated by inflammation. The muscularis mucosae was somewhat thickened, and both under the mucous membrane and within the muscularis mucosae the infiltration of spindle-cell elements with especially elongated nuclei was clearly seen. Among these cells was a plexus of corrugated and sometimes parallel fibrils. Particularly in the neighbourhood of small vessels, of which there were many, there was a tendency to orderly arrangement of cells. Near the mucosa there was a considerable inflammatory infiltration consisting chiefly of plasma and eosinophil cells. Fibroma and myoma were excluded by the histology of the tumour, and a diagnosis of neurofibroma was made. After the pathological report had been received the patient was given another thorough examination and neither on the skin nor on other parts of the body was anything found to indicate general neurofibromatosis. This case must therefore be accepted as an isolated neurofibroma of the stomach.

AVNI AKSEL,

Turkey Surgeon in Charge of the Haski Hospital Surgical Clinic.

Herpes Zoster with Underlying Pleural Rub

The following case is of interest because it illustrates one difficulty which may be encountered in the differential diagnosis of pleurisy. It is well recognized that pre-herpetic pain may be mistaken for pleurisy of pulmonary origin, but in this case of herpes there was in addition a pleural rub.

A woman aged 46, with a 20 years history of asthma and bronchitis, was admitted to hospital complaining of three days' pain in the left side of the chest on deep respiration and coughing. During the previous month her cough had been worse, with green and yellow sputum, but no haemoptosis. She was afebrile, pulse 80, respirations 20. Physical examination showed no abnormality except rales over the whole chest and tenderness over the seventh and eighth intercostal spaces in the posterior axillary line on the left side. No pleural rub was heard at this time. Radiographs showed evidence of chronic bronchitis but no abnormality in lung or in pleura in the area concerned. On the fourth day after admission a small crop of typical vesicles of herpes zoster appeared over the tender and painful area. Three days later a pleural friction rub appeared, directly under the area where the vesicles had appeared. The rub persisted for several days, and was not heard after the fourth day. At the same time, but the vesicles healed slowly, with scarring in the usual manner. No other evidence of pulmonary or pleural involvement appeared and she was discharged two weeks later. The blood sedimentation rate remained throughout within normal limits.

The interest of this case lies in the coincidence of the herpes with underlying pleural rub, and it was thought that this was due to herpetic lesions occurring on the surface of the parietal pleura. A similar case was reported by W. R. Brain (1932, 1940). It appears to be uncommon for a pleural rub to be heard with herpes zoster.

We wish to thank Dr. N. G. Hulbert for his help and for permission to publish this case.

Perforated Solitary Diverticulum of Caecum

Diverticulosis is a common condition of the large bowel, and much has been written about it. The condition was described by Cruveilhier in 1849, and in 1858 a case was reported to the Pathological Society of London (Jones, 1858-9). Since that time many statistics have been published. Generally speaking, the results show that diverticulosis and diverticulitis are rare under the age of 30, that they predominate in men, that they are usually confined to the distal half of the large intestine, and that single diverticula of the caecum are very rare. The case presented is that of a girl of 17 with a solitary diverticulum of the caecum which had become acutely inflamed and had perforated, giving rise to an "acute abdomen".

CASE HISTORY

The patient had had rheumatic fever twice in 1937 and once in 1938, but no previous attacks like the present one (Nov., 1942). Twenty-four hours before admission to hospital she had a sudden acute pain in the right iliac fossa and vomited shortly afterwards. The pain continued increasing in intensity up to the time of admission, and she vomited twice more. Menstruation was imminent, and the patient suffers from dysmenorrhoea. Examination showed her to be a well built, apparently robust girl, tongue dry, pulse 112, temperature 100. There was nothing abnormal in the chest. The heart was not enlarged, mitral first sound roughened, pulmonary second sound accentuated. The abdomen did not move well on respiration. Tenderness was marked in the right iliac fossa directly over the caecum. Guarding was present. No mass was palpable. A diagnosis of acute appendicitis was made, and laparotomy was done.

Operation.—The abdomen was opened through a McBurney incision, and on opening the peritoneum free faecal matter was seen lying over the caecum. The cause of this was found to be a perforated diverticulum on the lateral side of the caecum. The diverticulum was cone shaped and the base was about half an inch across. This area was acutely inflamed, and at the tip there was a perforation about the size of a split pea. The edges of the perforation were sutured and invaginated with two further rows of sutures. The wound was cleaned, and gloves and towels were changed. The appendix was normal, but it was removed. Sulphanilamide suspension was injected into the peritoneal cavity, and the wound was closed with drainage.

The patient made an uninterrupted recovery, and 15 days after operation a barium enema was given. The report was "Apparently normal colon." The patient was discharged five months later a further barium enema was given. The report was "Rectum and colon as far as caecum distended with barium. Large gut fills easily and slides up and down in ascending colon leaving no pockets of barium. Supine. Some segmentation of barium, but not pocketing. No abnormality detected to-day." The following day "Apart from a small amount of barium in the ampulla of rectum all the barium has been evacuated spontaneously—i.e., large gut is functioning well and without any disability whatsoever."

Two weeks later the patient came up complaining of a sudden onset of numbness and tingling in the right hand. There was pronounced tenderness over the roots of the fifth, sixth, seventh, and eighth cervical nerves. This responded rapidly to short-wave therapy, and the patient has been perfectly well since.

COMMENT

The case is unusual in view of the age of the patient and the nature of the lesion.

(a) *Age*.—Diverticula may be either congenital or acquired, and in this case, in view of the patient's age, the absence of the usual predisposing factors, and the broad neck, it is concluded that it represented one of the congenital type. Congenital diverticula have been described in ages down to 6 years (Hartwell and Cecil, 1910), but they are very rare: in 10,167 necropsies none were seen (Fifield, 1927).

(b) *The Nature of the Lesion*.—Cases of solitary diverticula of the caecum (Gabriel, 1937; Gordon-Taylor, 1938) and of perforated diverticulitis of the caecum simulating appendicitis have been reported (Fifield, 1927; Pereira, 1927), but these were of the typical indurated type in which differential diagnosis from carcinoma can only be made histologically after removal, or of the acquired type in which acute inflammation has supervened in the early stages and the narrow neck was ligated and the diverticulum removed. I was fortunate enough to see an example of the latter type, before any inflammatory changes had taken place, while operating on a ruptured ectopic pregnancy. There was a small diverticulum in the lateral wall of the caecum with a narrow neck, which was readily reducible. The remainder of the large bowel appeared free from diverticula.

The question arises, Why should this virulent infection occur in this one wide-necked congenital diverticulum? I do not attempt to answer this, but one wonders if the rheumatic condition played any part.

I wish to express my thanks to Mr. G. F. Stebbing and Dr. W. G. Evans for the radiological reports.

Definitive Hosts of a Species of *Diphylobothrium* causing Mass Infection of Trout in Reservoirs: Preliminary Note*

The reported infection of the trout in a South Wales reservoir with plerocercoids of a tapeworm of the family *Diphylobothriidae* (Duguid and Sheppard, 1944) has stimulated interest in the subject. The naturally infected definitive host in this outbreak was not identified. It has been suggested that the movements of population from endemic Scandinavian areas brought about by the war may have caused the spread of infection through the agency of man (*Lancet*, 1944).

In investigating an epizootic in the Dublin district it has been found that sea-gulls and cormorants from the area are infected with an adult tapeworm of the genus *Diphylobothrium*. In our opinion these birds are the naturally infected definitive hosts of the parasite in this district. Trout from reservoirs near Dublin are heavily infected with plerocercoids of the family *Diphylobothriidae*. Specimens showing all degrees of a gradual development from the typical plerocercoid as found in the fish to the fully developed tapeworm were present in the intestines of greater and lesser black-backed gulls (*Larus marinus* and *L. fuscus*), herring-gulls (*L. argentatus*), and cormorants (*Phalacrocorax carbo*).

So far as we can ascertain, the fact that gulls and cormorants act as definitive hosts of a species of *Diphylobothrium* which in its plerocercoid stage occurs in fresh-water fish has not previously been recorded in these islands.

Investigation of the infection at Poulaphuca reservoir, near Dublin, is proceeding, and fuller details will later become available.

Reviews

THE ENDOCRINE SYSTEM AND SEX

Endocrine Man. A Study in the Surgery of Sex. By L. R. Broster, D.M., M.Ch., F.R.C.S. With foreword by Sir Peter Chalmers Mitchell, D.Sc., F.R.S. (Pp. 144. 12s. 6d.) London: William Heinemann, 1944.

The misuse of endocrine therapy, too often seen in the recent past, could only be countered by exact experiment and a broad biological outlook. Mr. Broster's work on the adrenogenital syndrome has made him a recognized authority on the experimental and clinical aspects, and now in *Endocrine Man* he places his results in their appropriate position against a general biological background. He aims to do so in a way which he hopes is "not too technical for the keen and intelligent layman with a knowledge of general science." How far he has succeeded in this it is perhaps easier for the lay rather than the medical reader to assess; certainly there is plenty to interest the latter. The broad thesis is a consideration of the "instinctive tripod": tropisms, and the autonomic nervous system lying below the threshold of consciousness, and cerebral control which is associated with it. Instinct in its turn is defined as "inherited modes of reaction to bodily need and external stimulus"; one of the main pillars upon which the whole edifice of life has been constructed. Unlike the nervous reflexes, which are local and instantaneous, the instinctive responses are delayed, more complex, and influence the body as a whole. Delicate nervous impulses more and more become the rapid instrument of instinctive expression; and, although they multiply and increase its range, it is not reasonable to suppose that they entirely supplant the more primitive chemical tropisms. Indeed, Dale's work proves the contrary. The biology of the primitive instincts of growth, self-preservation, and reproduction are then discussed in some detail.

Coming next to his special topic Mr. Broster takes the view that, though the sex-determining mechanism normally depends on the chromosomes, this can be overridden by other factors. There is a male phase even in the female foetus, and over-activity of the adrenal cortex during that phase may upset the original female genetic bias. Since abnormal behaviour on the part of one gland upsets the balance of the others, the original genetic pattern may become obscured by polyglandular interaction. Though the pituitary, in Langdon-Brown's phrase, is "the leader of the endocrine orchestra" in post-natal life, the author thinks that during foetal life the adrenal cortex acts as leader. The functions of the individual endocrine glands are next considered with special reference to the light they throw on the problems of intersexuality.

Symbiosis and parasitism are discussed on the broader biological basis, and applied to "Siamese" and included twins, teratomata and new growths, as well as the occasional hostile parasitism shown by the foetus towards the maternal tissues. The final section, on the nature of man, deals with his evolution, attributing his rise to a somewhat sudden development of a brain which is giving him increasing mastery, though this form of control has masked but not mastered his animal instincts. The nervous and endocrine systems have been integrated and cannot be separated in a way which has hitherto been the method of their study, for each is dependent on the other.

This in briefest outline is the argument of a thought-stimulating book, covering a large field. The utilization of a central theme from which the argument develops is an attractive idea, and presumably represents the development of the author's own thoughts on the subject.

INDUSTRIAL MEDICINE IN THE U.S.A.

Essentials of Industrial Health. By C. O. Sappington, M.D. (Pp. 626; 63 illustrations. 42s.) Philadelphia, Montreal, London: J. B. Lippincott Company, 1944.

It is difficult to compare British problems of industrial medicine with those of the U.S.A., largely because they have no comprehensive national scheme of legislation such as our Factories Act. Each of the 48 States has its own special department concerned with labour and conditions of work. As a result there is wide variation in health provisions for the workers, and lack of universal standards. The absence of an American

National Health Insurance system makes the duties of the industrial medical officer and his ethical relationships with the general practitioner frequently at variance with accepted practice in this country. But the fundamental reasons for the existence of a health service in industry are similar—the care of the worker's health at the place of work by every possible means.

This book is different from others on the same subject which have recently come from America—it is the product of one writer. There is editorial sense of proportion and balance not found in similar textbooks written by groups of experts. While the author surveys the field widely—incidentally making few references to significant research work in this country—he nevertheless gives a wealth of detail on many important subjects, which obviously come from extensive personal experience over many years. Job analysis in relation to capacity for work and pre-placement medical examination, to take two important examples, are discussed at some length. Neither of these subjects has been sufficiently studied in this country. In chapters on industrial health exposures and hygiene Dr Sappington comes to the crux of industrial medicine—the need for the factory doctor to have an intimate knowledge of his industry and its different occupations, with a view all the time to prevention of accidents and ill-health. Obviously it is the author's view that occupational disease, though vitally important to workers in a few specialized industries, is not by any means a synonym for industrial medicine.

Any problem concerned with industry is difficult to divorce from wartime measures. The remarkable growth of American industry in its change over to products for war created a demand for more doctors for the factory, but as here these doctors have largely been appointed to the big concerns. The U.S. Census of Manufacturers in 1937 showed that out of 166,794 different manufacturing plants 160,245 employed 250 or fewer wage earners and out of 8,769,231 workers in these plants 3,810,626 worked in establishments employing fewer than 250 persons. This proportion compares closely with British figures, and shows that the difficulty of providing medical supervision on any comprehensive scale is similar. One important lesson learnt from reading this book is the urgent need for an authoritative British textbook of industrial medicine. In this respect we lag behind.

SULPHONAMIDE TREATMENT

Sulphonamide Therapy in Medical Practice. By Frederick C. Smith, M.D. M.S., F.A.P.S. Foreword by George Morris Piersol, M.D. (Pp. 368. Illustrated \$5.00.) Philadelphia: F. A. Davis Company, 1943.

The time has not yet come for a definitive work on this subject which that appears has an ephemeral value in being up-to-date, but is liable to supersession from that point of view within six months. If comprehensive enough, it will retain its value rather longer as a source of information about the treatment of less common conditions. Frederick C. Smith's *Sulphonamide Therapy in Medical Practice* differs from other similar books in its arrangement. After an introductory section, mainly on pharmacology and methods of administration, it deals alphabetically with diseases and their treatment with sulphonamides, starting with abscesses and appendicitis and finishing with urology and wound infections. At first sight this policy appears contrary to the most fundamental principle in this form of therapeutics—that one should treat not a disease but an infection by a particular micro-organism. Although this principle might well be more strongly emphasized in the text, it is not disregarded, and the arrangement chosen is perhaps justified on the score of ready reference and the direct applicability of the information to the individual diagnosis.

Different conditions are discussed rather unequally; there is naturally a longer section on pneumonia, and very short ones on atelektasis, filariasis, nephritis, and smallpox, but that on mastoiditis, consisting of 13 full case histories illustrating the author's content on that a mastoid wound can be closed without amputation if the cavity is filled with sulphanilamide or sulphazole, is disproportionately long. On the other hand, the section on gangrene is quite inadequate, citing only experimental evidence with no indication that there is any published experience to support it, although the first item of this

nature appeared in a well known American journal seven years ago. In spite of such defects, which are perhaps inevitable in any attempt to deal in this way with so vast a subject, and of a somewhat superficial outlook, this book will be found a useful source of information. There is a brief appendix on penicillin.

PAEDIATRIC HISTORY

Pioneers of Pediatrics. By Abraham Levinson, B.S. M.D. Second edition, revised and reset. (Pp. 119, illustrated \$2.00.) New York: Froben Press.

Under the title of *Pioneers of Pediatrics* Dr. Abraham Levinson has traced the history of this branch of medicine by means of short biographical sketches. It is a method which makes for easy reading, the author writes in an attractive style, and he has collected a large number of well chosen portraits to illustrate his text. Towards the end of the book he turns to what more resembles a history of disorders, for there is a chapter on "Investigators of Alimentary Disturbances in Infancy" and another on "Pioneers in Infant Feeding." In the latter some mention might have been made of the late Eric Pritchard. Indeed, British paediatricians of the past deserve rather more space. Cheadle is dismissed in three lines in company with Moller, and is erroneously credited with confusing scurvy and rickets. And there is no mention of John Thomson or Samuel Gee. In France Armand-Delille gets three lines, but there is no account of Marfan or Nobecourt. Of the American pioneers there is a fuller account, and the author, in any case, disclaims any attempt at presenting an exhaustive treatise. It is an attractive little volume, but the absence of an index is a pity.

Notes on Books

The exiled Poles who have come to this country since the war began have succeeded to a remarkable degree in making known among British people the science and learning of their country. In this they have been assisted, so far as medicine is concerned, by the foundation of a Polish Medical School within the walls of Edinburgh University and by the establishment in Edinburgh of the Paderewski Hospital. These enterprises, together with much else about Polish medicine, are described in one of a series of booklets entitled *Polish Science and Learning*, edited by the Association of Polish University Professors in Great Britain (Oxford University Press, 2s. 6d.). Here will be found articles by Polish doctors on medical education in Poland, Polish hospitals and sanatoria, the State Institute of Hygiene, the Polish system of social insurance, and the epidemics in Poland between the two world wars. The booklet includes also a full report of the Polish Committee of Health, set up by the Ministry of Labour and Social Welfare to deal with the problems of reconstruction. This report was the theme of Prof. Jurasz's recent Lloyd Roberts Lecture at the Royal Society of Medicine (*Supplement*, July 22, p. 18), but it is interesting to have a full account of the manner in which a Government in exile is anticipating in detail the health services which it hopes to institute on its return. The whole issue is full of ideas of reconstruction, and it is evident that the spirit of Copernicus, who was an economist and statesman as well as the father of modern astronomy, is stirring in a nation "which in the course of its history," as one of the writers says, "has risen again and again after the most dreadful ordeals to play a constructive part in the march of mankind."

Preparations and Appliances

HOT-AIR STERILIZER

Sterilization by hot air at 150 to 160° C is required for certain powders and oils and is the best method for glass apparatus, including all glass syringes. It also has some advantages for surgical instruments. A suitable oven for this purpose is rarely available in surgical units, whose staffs may therefore be interested in the "Stellax" Hot Air Sterilizer, of which we have received particulars from the manufacturers, C. H. Blackburn and Co. Ltd., 10, Gray's Inn Road, London, W.C.1. This apparatus is made for heating by gas, electricity, or internal spirit burners, the last named having the advantages that sterilization temperature is reached very rapidly and that operation is still possible when for any reason electricity or gas is not available.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY SEPTEMBER 2 1944

THE HEARING AFTER OTITIS MEDIA
IN INFANCY

In the treatment of acute otitis media, a potentially dangerous disease, attention has always been centred on achieving arrest of the inflammatory process in order to avoid the possible complications rather than to preserve the hearing. Naturally, danger to life is the first consideration, but the restoration of hearing is also important, and in more recent years this functional objective has not been neglected in the preoccupation of saving life. It is, however, commonly supposed that if the surgical treatment is satisfactory—by which is meant that the suppuration ceases and the tympanic membrane heals—the hearing will also be good, whether the treatment has been conservative or operative. But this seems to be largely a clinical impression unsupported by systematic testing of the hearing after recovery in a series of cases. On the other hand, as Nils Lundgren¹ points out, impaired hearing in children, as well as in many adults, is generally thought to be due to a previous attack of otitis. When observations have been made the hearing has been tested usually with the whispered voice unchecked by audiometric examination, or reliance has even been placed on the statement of the patient only. Bunch and Grove² examined audiometrically, between the ages of 7 and 16, a group of children who had had severe or recurrent attacks of otitis before the age of 5. Appreciable loss of hearing was found in 19%. This is one of very few such systematic examinations with the audiometer, and gives no information concerning the effect of treatment, whether conservative or operative, upon the preservation of hearing.

Generally, an operation which conserves the middle ear is recommended for a purulent otitis media which has not subsided at the end of four weeks; but there is no unanimity about this, and some have been inclined to recommend operation much earlier. This attitude, which had a number of supporters about ten years ago, is no longer the fashion, and the analogy with appendicitis is quite false. Early operation is therefore reserved for cases in which the threat of impending complications makes it urgent. Observations which Nils Lundgren has made were planned to elicit the influence which the line of treatment adopted, whether conservative or operative, may have on the hearing, and also on the relation between the duration of the otitis and the hearing. The investigation was based on a follow-up of 448 children up to the age of 3 who were treated for acute suppurative otitis media at Lund in the clinic of Prof. Dohlman during the period 1930–6. The follow-up was conducted during the years 1942–3, so

that the children had reached at least 7 years of age and were therefore able to co-operate in a reliable audiometric examination. The number of ears concerned was 709, of which 102 were on the right side, 85 on the left, and 261 bilateral. Conservative treatment was applied to 618 ears, and the simple mastoid operation was performed on 91. Of the 448 children treated 320 were re-examined (71%), and of the 709 ears treated 507 (72%) were re-examined. Cases of otitis due to tuberculosis, diphtheria, and scarlet fever were excluded from the survey. It soon became clear that impaired hearing was rare after an otitis of short duration, and the cases were therefore divided into two classes: of short duration—that is, of less than five weeks—and of long duration—that is, five weeks or more. It is to be noted that the hearing defects recorded are not necessarily due to the primary attack of otitis, but sometimes to recurrences also, which occurred in 129 cases (31%). Conservative treatment had been applied to 265 of the children re-examined, representing 413 ears, and of the 91 cases of mastoid operation 63 were re-examined.

In non-recurring otitis 223 cases (78%) were found to have normal hearing, and 61 (22%) had hearing defects. An analysis of these cases showed that the majority of the short cases of otitis recovered good hearing, and that the incidence of impaired hearing increased with the lengthening of the course of the attack. Thus in attacks lasting three weeks or less the incidence of hearing defects later was about 5%. For periods of four and five weeks the incidence rose to 19%, and there was a still higher rise after that. In 129 cases of recurrent otitis good hearing was found in 67 cases (52%). Here again the recurrences of short duration showed better hearing than those of long duration, and an analysis revealed that the short recurrences did not influence the incidence of impaired hearing. Thus the incidence of impaired hearing in the recurrent cases of otitis was 48%, compared with 22% in the non-recurring group.

The figures also support the general opinion that myringotomy has a favourable influence on the duration of the disease, as in 58% of cases subjected to myringotomy the duration was one to three weeks, as compared with 29% for spontaneous rupture. The figures also indicate that the tympanic membrane regained a normal appearance in most of the short cases of less than three weeks' duration, whilst the number of cases showing deformity of the tympanic membrane increased with the duration of the otitis. In non-recurring otitis there were persistent perforations in 3% of cases, whilst in recurrent otitis this figure rose to 12%.

In 709 ears with acute otitis the simple mastoid operation was performed 91 times, or in 13%. Re-examination of 63 of these cases showed that 30 of them (48%) had had recurrences, compared with 31% for the cases treated conservatively, though all were soundly healed at the time of the re-examination. Of the 63 cases 32 (51%) gave a normal audiogram, whilst 31 (49%) had hearing defects which were more common in the older children. In 42 of the 63 cases subjected to operation this was performed within five weeks of the onset, and good hearing was found in 25 and hearing defects in 23. On the other hand, in the 15 cases in which the discharge had lasted for five

¹ *Acta oto-laryngol.*, Suppl. 53, Lund, 1944.
² *Ann. Otol. Rhinol. Laryngol.*, 1930, 39, 1.

weeks or longer, with an average of seven weeks, there was full recovery of hearing in 7 cases and hearing defects in 8, but most of these hearing defects were much greater than those in the former group. Thus in the 63 cases subjected to the mastoid operation hearing defects were discovered by audiometry in nearly 50%, and in 19% these defects were gross enough to be discoverable by the whispering test. This percentage of hearing defects after the simple mastoid operation contrasts with the statements commonly made that as a rule the hearing returns to normal after this operation.

In comparing the results of conservative treatment and the simple mastoid operation certain difficulties arise. The cases treated conservatively must include a proportion of mild cases which heal quickly in three weeks or less, whilst those treated by operation include cases of extensive disease with more or less serious changes in bone. It is clear, too, that a case of otitis which heals in four weeks under conservative treatment is not comparable with a case subjected to operation in the fourth week, as the healing process in the ear in the latter case must last some weeks longer. A more useful comparison therefore, can be made by estimating what happens after about five weeks or longer, keeping in mind that after five weeks the percentage of impaired hearing in conservatively treated non-recurring otitis rises steadily, and is nearly identical with that of recurring otitis. The average in these cases gives 51% of good hearing, which is the same (51%) as the average for good hearing after the mastoid operation. It appears from this that operation is the best form of treatment if the suppuration has persisted for six weeks without showing signs of improvement at the end of four or five weeks, for impairment of hearing is more severe where the suppuration has persisted for five weeks or more before operation. The best prospect, therefore, of recovery of good hearing is to perform the operation before the suppuration has continued for more than five weeks.

The author has analysed his figures in greater detail than can be given here, and they have yielded important information on other points, but they give concrete support to the clinical impression that the mastoid operation should be performed late but not too late, and that a vast number of the hearing defects found in adult life have their origin in childhood.

CIVILIZATION AND MEDICINE

Once man turned from merely being a food hunter to becoming also a food-producer, civilization could begin. But its course has been interrupted and powerfully deflected by recurrent war, pestilence, and famine. Moreover, civilization itself has played a part in the propagation of disease. Prof H E Sigerist, well known as an authority on the history of medicine, has traced out some of these interactions in a fascinating way.¹ It was hunger in addition to their characteristic aggressiveness which drove the Germanic tribes westward to destroy the Roman Empire. It was plague that changed Justinian's empire from Roman to Byzantine Greek, wherein Con-

stantinople remained static for nearly a thousand years. It was the Black Death that changed the face of Europe and cleft the Middle Ages in twain. But this great disaster nevertheless played an important part in clearing the way for the rise of a new economic order, and incidentally killed off nearly all the lepers, who thenceforward ceased to be a social problem. This epidemic, by the way, was not called the Black Death, as here stated and generally believed, because of the lividity of sufferers from the haemorrhagic type that name was only given by later centuries, for contemporary writers it was the "Great Death." When Sir Arthur Shipley said the struggle for supremacy between insect and man was still in doubt he was not jesting. The mosquito has laid fertile fields desolate, has sapped the vitality of nations, and is still a world problem. The rat flea has slain its millions by plague. Charles V overthrew Francis I and sacked Rome, only to be defeated in his turn by the louse at Naples. Apart from such vectors, human carriers of typhoid fever and dysentery have brought wars to an inglorious end. The advance of medical science has changed all that, so that wars can now be fought out to a more bitter finish.

Until the Industrial Revolution population did not change much in density, and it found authority unable and unwilling to face the new problems thus created. Yet as long ago as 1700 Ramazzini had called attention to the importance of industrial diseases. Apart from this, a low standard of living, poor housing conditions, and lack of food and clothing and fuel have always been major causes of disease. Tables of mortality, grouped according to income level, bring that out clearly. Nor, as Dr Sigerist shows, is that simply due to an inferior earning capacity of the incompetent. In the depression in the USA between 1929 and 1932 the disability from disease increased in accurate proportion to the fall from the previous income level, whatever the social class.

Dr Sigerist develops in an interesting way the evolution of medicine through magic, religion, and philosophy towards a scientific basis. So long as disease and death were regarded as imposed by external agents, human or divine, magic seemed the logical antidote. From the belief in the mystical properties of herbs a number of useful remedies were empirically discovered. Religion brought in the idea of disease as a punishment for sin, for which sacrifice and penance were the appropriate penalties. Magic and religion mingled in such superstitions as touching for the King's Evil, a corollary to the doctrine of the divine right of kings. It originated in France, and Dr Sigerist states that Henry I was the first English king to practise it. But Sir Raymond Crawford traced it back to Edward the Confessor, whom he regarded as more Norman than Anglo-Saxon. The influence of religion was undoubtedly responsible for the care of the sick and suffering, previously hospital services, apart from ancient Greece, were reserved for the soldiery. By philosophy Dr Sigerist apparently means the basing of medical practice on some theoretical conception. Thus, the doctrine of signatures, in addition to its magical aspect, maintained that similarity of structure in a plant to the diseased organ indicated the appropriate cure. The doctrine of humours also falls into this class. Thus Galen in main-

¹ *Civilization and Disease* Oxford University Press (22s. 6d.)

taining that a disease which was hot and moist was to be cured by drugs that were cold and dry was a true "allopath" in the way which we, despite the homoeopaths, are not. Iatrochemists and iatrophysicists were similarly chained to a formula.

The scientific study of medicine began with Vesalius and his anatomy, to be followed by Harvey's application of physics to physiology. Yet in the seventeenth century disease was still interpreted in the traditional philosophical way, until Morgagni related disease to a lesion in some organ. From the organ, pathology proceeded to investigation of the tissues and then of the cell. Meanwhile, therapeutics lingered until the study of function and of invasion by various types of parasites led to new pharmacological conceptions. That all this led to a too materialistic view is now realized, and in the development of psychotherapy, not divorced from religion, Dr. Sigerist hopes much. Incidentally his analysis of tarantulum as a mass neurosis is full of interesting information. The crisis through which civilization is now passing he sees as the result of technology outrunning sociology; in that process medicine has shared. We have built ingenious machines but not the requisite social and economic organization to match. We have developed rapid transport without methods of peaceful co-operation between nations. The machine age calls for social and economic adjustments, not just in the medical world but everywhere. The health and welfare of every individual are the concern of society, and the conclusion is that human solidarity, beyond the boundaries of nationality and race and creed, is the true criterion of civilization.

FURTHER NOTE ON PENICILLIN PRODUCTION

Two recent articles in American chemical engineering journals^{1,2} give an illuminating picture of the effort that has gone to produce the penicillin now being used so extensively for the Allied Forces and to which we referred briefly in a recent annotation. In reviewing these two articles we are not unmindful of the contribution to the common store that has come from this side of the Atlantic, but, for reasons that will appear later, British production is at present only a fraction of the American. Pure sodium penicillin has a strength of 1,650 Oxford units per milligramme. The therapeutic concentration of penicillin—i.e., the strength required to check bacterial growth in body fluids—is 200 units per litre, or less than one-eighth of a milligramme. The maximum concentration of penicillin in the original culture media used to grow the mould was about 2,000 units, or 1 mg. per litre. At least half of this was lost in the process of concentration and extraction. Penicillin is extremely labile, and easily destroyed by heat, contamination by bacteria or moulds, and traces of metals or foreign chemicals. It can be preserved only under dry sterile conditions. The difficulties were so great that it seemed doubtful whether penicillin ever could be produced on a commercial scale. The decision to try to manufacture penicillin involved the expenditure of millions of dollars, and at the time the decision was made, in 1940 and 1941, the sceptic might well have doubted whether the drug was worth the trouble.

Fortunately the discovery was fairly early made that the yield of penicillin could be increased tenfold or twenty-

fold by adding corn-steeping liquor to the medium on which the mould was grown. The next step was to apportion available resources most wisely between the three different methods of growing the mould—surface culture, submerged culture, and culture on bran. Surface culture, in which the mould is grown on the surface of a thin layer of medium in flasks or milk bottles, is the original laboratory technique. It has the advantage of being relatively fool-proof, but the disadvantage of requiring a vast amount of space and labour. To process 10,000 gallons of medium requires as many as 100,000 or 125,000 bottles, which is several days' run in even the largest of the plants. In the submerged process the mould is grown in tanks containing several thousand gallons of medium; the difficulties of aerating and agitating these large volumes of fluid without allowing contamination to occur are immense, and they have taxed human ingenuity to the utmost. In the bran process the mould is grown on the surface of moist bran in trays or drums. The difficulty here is that bran is a poor conductor of heat. It is therefore difficult to sterilize the bran initially and difficult to dissipate the heat that is produced by the fermentation process. When the fermentation cycle is complete the penicillin still has to be harvested. The concentration is only of the same order as bromine in sea-water. Separation and recovery have to be carried out with extreme care owing to the instability of the penicillin, and the material is finally frozen and dried from that state in the same fashion as dried plasma is produced. An immense amount of special equipment has been needed for this purpose. Penicillin as finally supplied to the physician is a yellow or brown powder, containing 100 to 500 units per mg., or about 8 to 30% of sodium penicillin.

All this has needed the erection of more than a score of factories and the expenditure of 20 million dollars. The decision to manufacture the major proportion of supplies of penicillin in the U.S.A. and Canada has largely turned on the demands it has made on labour, factory space, and technical equipment at a time when we were already fully engaged in our war effort. Production is finally expected to reach 200×10^3 units a month, or 9 lb. of pure penicillin a day. A severe case requiring penicillin therapy will need about a million units, for which the present cost is 47.5 dollars—a cost that will certainly fall. It is clear that it will not be long before penicillin is generally available. Some of the unwise publicity that the drug has received may then recoil in disappointment. Penicillin is the best of all antiseptics for serious wounds. It is superior to the sulphonamides in the treatment of venereal disease. For both reasons it is of immense value to the military physician, who has his patients under his complete control. On the other hand, penicillin is not a cure-all and it is not effective by mouth. For general illnesses it must be given by frequent or continuous injection. Adequate treatment of an illness with penicillin is as difficult as the treatment of diabetic coma with insulin. Inadequate treatment will merely waste and discredit a drug which it has taken so much thought and labour to produce.

ECONOMY OF DRUGS IN WARTIME

A revised edition of the M.R.C. War Memorandum No. 3 on *Economy in the Use of Drugs in Wartime* has been published by H.M. Stationery Office, price 3d. This memorandum, first printed in March, 1941, expresses the considered opinion of the Therapeutic Requirements Committee set up by the Medical Research Council in consultation with the Ministry of Health. The body of the memorandum takes the form of a list of drugs grouped

¹ Elder, A. L., and Monroe, L. A., *Chem. and Metallurg. Engng.*, March, 1944.
² Cozhill, R. D., *Chem. and Engng. News*, April 25, 1944.

according to their therapeutic value and their availability in wartime, the main lines of the original list being followed. Some change, however, has been made in the method of classifying the drugs. As the war has proceeded it has become increasingly difficult to keep separate the ideas that a drug, on the one hand, may be readily available and, on the other, may be essential to the practice of medicine. The shortage of one drug may lead to an unusually large demand for another, which in consequence becomes in short supply. Stocks of drugs of all kinds tend to be smaller in time of war, and changes in the supply position may occur quickly; too rigid grouping may thus defeat its own object. The classification adopted in the new edition is as follows: (A) drugs which are important therapeutic agents and which should be made available so far as practicable; (B) drugs which are needed for certain purposes but of which supplies are limited; (C) drugs which are not essential and do not justify importation or manufacture for home use in wartime. The group "A" now aims at indicating simply those drugs which are eminently of value as therapeutic agents. It is left to the good sense of the prescriber to use drugs in group "B" only for the purposes for which they are known to be of substantial value; he should not prescribe any "B" drug as a placebo. The committee makes it clear that the list is primarily intended to secure the wisest economy in the use of drugs for consumption in this country and that other considerations may affect the importation or manufacture of drugs for the export trade. Responsibility for providing drugs and therapeutic substances is now vested in the Ministry of Supply, which acts in consultation with the Ministry of Health. Both Ministries are represented on the Therapeutic Requirements Committee.

In April, 1942, a memorandum on *Economy in the Use of Bactericides*, prepared by the Therapeutic Requirements Committee, was issued by the M.R.C. and reproduced in our issue of April 11. This document has now been revised and appears as an appendix to the new edition of the main memorandum.

PROGNOSIS IN GASTRIC CANCER

Carcinoma of the stomach claims every day over forty victims in Great Britain alone. Its prophylaxis, early diagnosis, and surgical treatment are consequently problems of the first importance. Carcinoma probably never develops in a healthy stomach, so that the study of the causes, prevention, and treatment of precancerous gastric conditions, such as achlorhydric gastritis, chronic gastric ulcer, and adenomatous polypi, holds out much hope for reducing its incidence in the future.¹ Early diagnosis depends largely on improving the education of the medical student, so that the practitioner of the future will learn that digestive symptoms occurring after the age of 40 which do not promptly disappear with simple treatment call for thorough investigation. Given the opportunity, the biochemist, radiologist, and gastroscopist can diagnose carcinoma in a large majority of cases by the time that the first symptoms have appeared and before any tumour is palpable. Unfortunately, however, the surgeon rarely sees a case in which symptoms have not been present for many weeks or months before the patient has undergone a thorough examination. Even with the delay in diagnosis which is still almost universal the prospects of successful surgery in carcinoma of the stomach are better than is generally believed. This is well seen in surveys recently published on work done in the Mayo Clinic.^{2,3} The pro-

portion of patients with cancer of the stomach admitted to the clinic and considered suitable for operation rose from 54% in 1928 to 67% in 1942, and of these the percentage in whom the growth was resected increased from 48 to 58, whilst the operative mortality fell to 6.7% in 1942, the lowest on record in the clinic. The last figure does not leave much room for improvement, but one can still hope that the operability rate will materially increase with earlier diagnosis and by extending the scope of partial gastrectomy. Of over 10,000 patients who survived resection between 1907 and 1938 29% were alive at the end of five years, after which the chance of survival was about the same as for persons of comparable age in the general population. Actually 6.3% had lived for twenty-five years or longer. It is important to remember that complete gastrectomy does not interfere with nutrition and that it does not necessitate any considerable dietetic restriction. The development of microcytic or macrocytic anaemia is also easily prevented.

The operability of cancer of the stomach has shown considerable advances during the last few years owing to the fact that lesions formerly regarded as inoperable on account of their inaccessibility are now being successfully removed. This is true particularly of lesions involving the cardia, which can often be successfully removed by the transpleural approach, the advance being thus perhaps more due to the work of the thoracic than to that of the abdominal surgeon.

WHAT THE PUBLIC KNOWS ABOUT HEALTH

The Ministry of Health determined recently to find out how far its statements about venereal diseases, published in the newspapers and popular magazines, had attracted the attention of the public and what was the state of public knowledge about these diseases. The task was entrusted to a body called the Wartime Social Survey, which is the Government's social research unit and exists to provide any Department with information not available from other sources which may be needed for the shaping of policy or administration. The results were given to the June meeting of the Royal Statistical Society in a paper by two of the investigators—Kathleen Box and Geoffrey Thomas. A sample of people aged between 14 and 50, equally divided between the sexes and from different occupation groups, were chosen by the interviewers, who were told to abandon the interview if the informant seemed reluctant to answer owing to a distaste for the subject or excessive shyness. It is worthy of remark that only 3% of the interviews were abandoned, and that 60% of the people were "very interested, helpful, and willing." Of the sample taken, 86% had seen the Ministry's statements, and 72% said they had read them. Of the men 81% and of the women 62% answered that they knew what venereal diseases were, and of these, 11% of the men and 6% of the women declared that they "knew all about venereal diseases." Of the remainder 17% of the total sample were "not quite sure" or returned a vague answer, and 11% "did not know what these diseases were." It appears that rather more than a quarter of the people interviewed, whether or not they knew anything about venereal diseases before they saw the Ministry's statements, had learned something from those publications. The results suggest—and it will not surprise anyone even to-day—that the group most in need of education is the under-20 group, and that men in the later age groups and in the higher income groups are, on the whole, the best informed.

A further inquiry was undertaken to discover how much parents knew about the causes, dangers, and methods of

¹ Hurst, A. F., *Lancet*, 1938, 1, 553.

² Walters, W., *Proc. Mayo Clin.*, 1943, 13, 595.

³ *Arch. Surg.*, 1943, 46, 959.

prevention of diphtheria. A sample of parents with children under 14 years was interviewed, and the inquiry covered two types of districts—those in which there was a high rate of immunization and those in which there was a low. Asked "What do you know about the cause of diphtheria?" 51% of the parents simply did not know, 24% declared it to be poor health, bad sanitation, or dirt, and 25% thought it due to contagious illness or germs. The extent of knowledge was greatest in the upper economic group. The percentage of parents in good immunization areas who did not know the cause of diphtheria was 27, and in the bad areas 56. But three-quarters of the parents knew what the dangers of diphtheria were, and 60% in all the groups believed in immunization as a preventive.

The Wartime Social Survey is now engaged in experimentation on a method of obtaining month-to-month statistics relating to the incidence of illness in the whole population between the ages of 16 and 64. It is hoped that if this method is successful it will be possible to keep a constant check on the health of the people. The figures will permit of analysis into age groups, occupations, and certain environmental factors. The organization is also spreading itself into other fields, such as the cooking habits of the people, the meals eaten by people doing different sorts of work, public attitudes towards food rationing and shortages, clothing needs in selected occupation groups, the response to the "coughs and sneezes" posters, domestic heating and lighting problems, and, in Scotland more particularly, housing questions. Such methods are no doubt very useful provided their limitations are understood and they are not regarded as a kind of magic. In eliciting opinion as compared with facts they may prove very deceptive.

TRACING A CARRIER THROUGH SEWAGE

A new example of what can be done by modern bacteriological detective methods is described in a recent paper by G. J. G. King.¹ An essential proceeding in this investigation was the phage typing of paratyphoid bacilli, which was described by Felix in this *Journal* last year.² The definition of separate types of *Bact. typhosum* by their susceptibility to different strains of bacteriophage, originally developed by Cragie and Yen, has been practised extensively in this country by Felix and now extended

to *Bact. paratyphosum* B. This method, to which there is no alternative among the enteric group of organisms,

bless type distinctions to be made which serve the same purpose as, for example, serological typing among haemolytic streptococci. It can thus be decided at least that a particular case or carrier is unconnected with a prevailing epidemic if the type of his organism is different from that prevalent in the district. The story told by King concerns paratyphoid fever in Glamorgan, where an outbreak due to Type 1 occurred in 1941. During this epidemic a single strain not then identifiable as belonging to any recognized type was isolated from a case in another part of the county. In March, 1943, the sewage effluents from a factory were examined for a purpose unconnected with the earlier outbreak, and by the use of desoxycholate citrate broth *Bact. paratyphosum* B was isolated and found to belong to the newly recognized Type 3A. The evident existence of a carrier among the employees of this factory demanded the examination of individual samples of faeces, and this led to the identification of the source of the

organism found in the sewage. This proved to be the man who had had the disease in 1941 and whose strain differed from that in the prevailing epidemic. Re-examination of the culture obtained from him two years previously and not then identified showed it to be of Type 3A. This episode gives some idea of what can now be done both by the use of highly selective culture media and by phage typing, studying the epidemiology of enteric fever. It is the first occasion on which the existence of a carrier has been detected by finding his organism in sewage.

IS NITROUS OXIDE "SAFE"?

Academic discussions about the "safety" of any particular anaesthetic agent, or the pathological effect it produces on the various organs of the body, are meaningless without any reference to the fact that during the administration the patient should receive an adequate supply of oxygen. Complete oxygen lack means death in a few minutes, but even partial oxygen lack, if prolonged, may result in irreparable damage to nervous tissue. In extreme cases of oxygen deprivation death has resulted after a period of unconsciousness and convulsions. In others varying degrees of mental impairment have become evident. Anoxia is an inseparable partner of nitrous oxide, an agent that has been lauded for many years as "harmless" and "non-toxic." Informed opinion is still not agreed about the precise mechanism whereby this gas produces anaesthesia; but no one doubts that deprivation of oxygen inevitably accompanies anaesthesia from nitrous oxide. It is in addition a "weak" anaesthetic, and muscular relaxation is difficult to attain with it. Therein lies the pitfall for the unwary. A desire to benefit the patient by "pushing" this gas by cutting down the oxygen instead of reinforcing it with a more powerful agent may have unfortunate results, as Courville¹ in America—and occasionally the coroners' courts in this country—has shown. Nitrous oxide and oxygen has a wide sphere of usefulness, and when given by an expert is a safe anaesthetic and is followed by a minimum of after-effects. Nevertheless the fact that nitrous oxide is harmless when used to produce a minute or so of semi-aphyical unconsciousness in the dentist's chair should not lead the inexperienced to suppose that it is equally harmless when used by them in abdominal surgery. It is true that after adequate morphinization good results are obtained by the few experts in the use of this gas. A special and potentially dangerous technique is followed. This in inexperienced hands is fraught with disappointment if not carried out boldly, and with danger if it is. It is also true that during abdominal operations surgeons are sometimes deliberately led to believe that only nitrous oxide is being used when in fact the gas is surreptitiously diverted over one of the more potent liquid anaesthetics. Nitrous oxide here could well be replaced by compressed air, or, alternatively, equally satisfactory results would follow the old-fashioned method of pouring the liquid anaesthetic on an open mask. The teaching that nitrous oxide is "harmless," "non-toxic," and "the least dangerous anaesthetic" should always be qualified, and the limitations and indications of this anaesthetic carefully defined. Statements about its harmlessness should not be made by physicians unfamiliar with the requirements of modern surgical technique. "A whiff of gas" may be dangerous if taken literally, and the phrase "fit for gas" when it is meant to imply "unfit for anything else" should disappear from the case notes of ill patients requiring extensive operation.

Reports of Societies

TREATMENT WITH PENICILLIN

At a meeting of the Fever Group of the Society of Medical Officers of Health, with Dr ANDREW TOPPING in the chair, a discussion on penicillin was opened by Sir ALEXANDER FLEMING, who demonstrated graphically blood levels and rate of disappearance of penicillin after administration by various routes. He also described the slide cell and the capillary culture methods of estimating penicillin content of the blood by bacteriostatic tests.

Ten Civilian Cases

Dr A. DOLPHIN (L.C.C.) gave an account of 10 cases treated at the North Western Hospital, L.C.C. 6 cases of puerperal septicaemia, of which 3 were due to anaerobic streptococci, 2 to *Staphylococcus aureus*, and one to *Strept. haemolyticus*; 3 cases of suppurative meningitis, of which one was caused by the *Strept. haemolyticus*, the others by pneumococci. The tenth case was an infective endocarditis due to *Strept. viridans*. In each instance the causative organism was isolated and proved to be penicillin sensitive.

In all three anaerobic streptococcal septicaemias there were lung complications on admission, after two days treatment with penicillin blood cultures became negative, accompanied by decided clinical improvement. The improvement was not maintained, though the blood remained sterile, and two of the patients died from multiple lung abscesses, the third from intestinal obstruction due to multiple peritoneal adhesions. This patient gave a strongly positive blood and cerebrospinal fluid Wassermann reaction before penicillin administration, thereafter the blood W.R. became practically negative but the CSF W.R. remained strongly positive. At no time was the drug detected in the CSF.

The first patient with *Staph. aureus* septicaemia had mitral stenosis, haematuria, and skin petechiae. The blood became sterile after two days' penicillin treatment. Death occurred 11 days later from uraemia, confirmed at necropsy by the presence of chronic nephritis lesions. The other patient was treated on the 9th day of disease, and after a first course of 790,000 units she relapsed and two further courses were necessary before recovery.

The patient with *Strept. haemolyticus* septicaemia was treated on the 12th day of disease. She recovered, but was left with permanent valvular heart damage, probably well advanced before treatment.

The haemolytic streptococcus meningitis case—an infant of 5 months—received treatment on the 8th day of disease. The drug was given intrathecally, intramuscularly, and (after bilateral mastoidectomy) into the mastoid wounds. The CSF became sterile, but subarachnoid block developed and signs of local cerebral irritation. The mastoid wounds were reopened and the brain unsuccessfully needed for pus.

Of the two cases of pneumococcal meningitis one had severe septicaemia on the 29th day of disease and subarachnoid block when admitted for treatment. Penicillin was injected into the cerebral ventricles, cauda magna, spinal theca and intramuscularly. The blood became sterile, but the meningitis did not respond and the patient died on the third day of treatment. Necropsy was refused. The second pneumococcal meningitis case likewise did not respond to penicillin owing to subarachnoid block, confirmed at necropsy.

Treatment of the *Strept. viridans* septicaemia was started on the 4th day of disease when the patient appeared to be dying. After 24 hours on penicillin the blood was sterile, the temperature normal, and the general condition considerably improved. Subsequent blood cultures were sterile, and the patient had not relapsed.

All the septicaemias except the last case were treated by intermittent intramuscular injections of 15,000 units of penicillin, with intravenous injections initially in a few cases. The injections were given 3 hourly at first, and therapy was stopped gradually either by lengthening the intervals between injections or reducing each dose. The last case was treated by continuous intravenous drip, 100,000 units in 24 hours, treatment lasted 15 days and was stopped suddenly. A constant blood bacteriostasis was maintained, but the method had the serious disadvantage that thrombophlebitis was a common occurrence and all the available veins might be used during a prolonged course of treatment.

Dr Dolphin added that a falling pulse rate was a more reliable guide to successful therapy than the temperature, because fever often increased when penicillin was first given. The earliest signs of success were better appetite and sleep and relief of pain and malaise. Occasionally the blood urea rose during therapy, and a falling white cell count, if originally high, or a rising count, if originally low, because of previous administration of sulphonamide, were favourable signs.

Discussion

Dr W. GUNN (L.C.C.) suggested that the results appeared worse than the clinical facts indicated, all three anaerobic streptococcal cases were very toxic and obviously bad risks, and two of the three meningitis patients were moribund on admission. It was probable that a more generous dosage, preferably using a continuous method, would have yielded better results. Intermittent administration with consequent intermittent bacteriostasis and gradual withdrawal of the drug might conceivably induce drug resistance, as Schmidt and Scaler¹ showed experimentally with pneumococci in mice. The last case described—a bad risk—was treated by the intravenous route followed by sudden withdrawal with conspicuous success, as was a more recent case of staphylococcal septicaemia after mastoidectomy not included in this series. Only extreme scarcity of the drug could justify inadequate dosage, which, as seen in the fifth case requiring three courses of treatment, was liable to prove uneconomical in the long run.

Dr J. M. ALSTON (L.C.C.) described the case of an elderly man with an anaerobic streptococcal septicaemia who responded repeatedly though temporarily to intravenous injections of a crude preparation of penicillin. He was struck by the marked and immediate clearing of the mental condition in desperately ill patients after quite small doses. In animal experiments he had found *Leptospira icterohaemorrhagiae* sensitive to penicillin, but treatment of affected guinea-pigs had to be undertaken early and with big dosage.

Dr ROBERT CRICKSHANK (L.C.C.) stressed the value of quantitative blood culture in the prognosis of generalized infections. For example, in staphylococcal infections an increase in the bacterial count from 20 to over 100 organisms per c.c.m. of blood within 24 hours meant a grave prognosis. Staphylococcal septicaemia was often complicated by renal damage, which resulted in a reduced excretion of penicillin, so that the drug could still be demonstrated in the blood 6 to 12 hours after the standard intramuscular dose of 15,000 units. The outstanding feature at necropsy in the patients with anaerobic streptococcus septicaemia was the multiple lung abscesses secondary to the primary septic thrombophlebitis in the pelvic veins. If these infections could be diagnosed and treated early, he was sure that penicillin therapy would be effective.

PENICILLIN FOR CIVILIANS

The following brief memorandum on the selection of cases for treatment with penicillin under the arrangements for civilian—noted in these columns on Aug 19 (p. 250) has been issued by the Ministry of Health.

The list of diseases for which penicillin may be used is as follows:

1 Conditions which should be admitted to hospital if the case is otherwise suitable for treatment with penicillin.

Staphylococcal Infections—Septicaemia. Early acute osteomyelitis. Severe carbuncle, cavernous sinus thrombosis, or any other life endangering infection.

Haemolytic Streptococcal Pneumococcal, and Meningococcal Infections—Any life-endangering infection (septicaemia, pneumonia, meningitis) which has failed to respond to adequate sulphonamide treatment.

Gas Gangrene

2 Conditions deserving special consideration, which may be treated if supplies are sufficient: (a) Injuries of the eye and infections of the conjunctiva and cornea. (b) Sepsis in wounds and burns. (c) Infections of the skin resistant to other forms of treatment (syphilis, impetigo, etc.). (d) Sulphonamide resistant gonorrhoea. (e) Acute empyema and pyogenic infections of the pleura as a complication of tuberculosis. (f) Traumatic lesions, including compound fractures of any bone, extensive muscle injuries, facial injuries, injuries necessitating suture of tendon or nerve, thoracic injuries (haemothorax), and post-traumatic pneumonias.

If supplies are sufficient, approved departments and hospitals specializing in ophthalmology, neurosurgery, thoracic surgery, burns, etc., may be given a supply of penicillin.

3 Conditions which will not be treated are those caused by organisms not known to be susceptible to penicillin (including rheumatic fever, ulcerative colitis, and all other intestinal infections). Bacterial endocarditis and syphilis will also be excluded.

ACADEMY OF MEDICAL SCIENCES OF THE U.S.S.R.

The announcement just received of the formation of an Academy of Medical Sciences of the U.S.S.R. indicates a recognition in that country of the need to reverse the trend towards narrow specialization which has characterized scientific progress (including medicine) in recent years. The academy, whose members to start with will number 56, is to be set up under the People's Commissariat of Health, and will have three departments: (1) medical biology; (2) hygiene, microbiology, and epidemiology; and (3) clinical medicine. Each of these will be composed of several scientific institutes, 25 in all, many of which will be, in effect, an extension of the appropriate section of the All-Union Institute of Experimental Medicine which is being merged with the academy. An organizing bureau has been set up under the chairmanship of the People's Commissar for Health of the U.S.S.R., and among the first members are N. N. Burdenko, A. I. Abrikosov, N. I. Grashchenkov, B. D. Petrov, and S. G. Suvorov. Commenting in *Izvestia* recently on the tendency to work in isolation in the medical field, Abrikosov said there had been no exchange of experience and achievement between medical men, no mutual help, and no co-ordination of work. In addition, there had been mistakes in the direction of scientific investigation. Biology, histology, physiology, pathological morphology, and general pathology and pharmacology (including chemotherapy), which would be the field of activity of the department of medical biology, were of the first importance to an understanding of the nature of disease and the discovery of new methods of diagnosis and treatment. They were the foundation of medicine itself; without more knowledge of the structure of chemistry and normal functions of the human organism further advance in medical science would be impossible. It was hoped that the new academy would not only benefit medicine in the U.S.S.R. but would attain a position of repute in the estimation of medical men the world over.

BIRMINGHAM ACCIDENT HOSPITAL

The new reception and out-patient departments at the Birmingham Accident Hospital were opened on Aug. 14 by the Minister of Health. The Lord Mayor of Birmingham as president of the hospital was in the chair. Declaring the new block open, Mr. Willink said he appreciated being able to lay aside wartime duties for a day to see something that was of a constructive nature with important implications for the future. In spite of much difficulty Birmingham had, in the middle of a war, gone ahead with an experiment on accident treatment that was being closely studied by other communities. His advisers at the Ministry felt that this type of hospital would have a permanent place in the future hospital services. Three qualities of the hospital impressed him. First, imagination had been used to transform an old building so effectively, and to link it with close ties to industry; he liked the idea of special rehabilitation workshops; secondly, the full development of modern resources and medical skill; even the waiting hall was a bright and cheery place; and, thirdly, this was an example of citizenship and of co-operation—a spirit which he had hoped would pervade the new national health service. He saw here close collaboration between the city authorities, the university, and the hospital. It was clear that the people as a whole, and especially those in industry, were taking a deep and personal interest in the development of new and specialized methods of accident treatment.

Mr. George Tomlinson, Parliamentary Secretary to the Minister of Labour, who was also there, said that the success of modern hospital practice was largely due to the application of sound common sense in the treatment of humanity. Many big words, sometimes frightening ones, were used to describe the work of the medical profession: occupational therapy, for instance, was no more or less than curing by work. Rehabilitation, in the real sense of the term, must include a full sense of security. A scheme which did not recognize its economic implications could not be successful. Before the war 200,000 persons were unemployable through disablement. Because of the urgency of national effort all but 18,000 of them had taken up work in some form or other. Rehabilitation was one of the great social advances which had emerged from this war.

L. Dungal (*J. Amer. med. Ass.*, 1944, 125, 20), during an epidemic of measles in Iceland in 1942, injected 302 persons with convalescent serum. 139 (70%) remained free of symptoms and most of the rest got the disease in a much milder form than the unprotected. The dosage was 1 c.cm. of serum for each year of age, but never less than 2 c.cm. and up to 20 c.cm. for adults.

THE DOCTOR'S OATH

No document in all medical literature is quoted so often as the so-called Hippocratic Oath. Books and articles on it mount to a veritable library. There are many and divergent opinions on its origin, meaning, and application. Perhaps no part of it has been so debated as its ethical rules. To these have been ascribed a timeless validity. Critical reflection may raise a doubt. "With purity and holiness I will pass my life," for example, presupposes recognized standards of these qualities. But neither the purity nor the holiness of a small Greek sect or guild in the fifth century B.C. meant at all the same as they mean in our Western civilization two and a half millennia later. Attention is often directed also to the prohibition of abortion. This was, in fact, practised freely in Greek times. Why not in a world in which it was considered justifiable to expose infants? Moreover, there are open references to abortion in books of the Hippocratic Collection. With many such points in mind scholars have divided up the Oath, distributing its parts to various dates between the sixth century B.C. and the third A.D.

Dr. L. Edelstein of the Institute for the History of Medicine at Johns Hopkins appropriately opens a new series of publications from that institution with a searching and original review of the whole problem.¹ He reaches the conclusion that the Oath is, in all essentials, a single document. He regards it as uniformly conceived and saturated throughout with Pythagorean philosophy, which should, perhaps, be called the Pythagorean religion. In spirit and letter, in form and content, it is a Pythagorean manifesto. Dr. Edelstein believes it to be intelligible only as such. He holds that the Oath was outlined towards the end of the fourth century B.C. He gives good reason for believing it to be post-Aristotelian, and about a century later than Hippocrates of Cos. Apart from evidence as to its nature, we know that it would have been timely in the later fourth century, when many attempts were made to improve medical conditions, while at the same time Pythagorean ethics were being elaborated and formulated. Specifically it is often noted that the Oath is not a legal enactment. It is rather a solemn promise, guaranteed only by the conscience. This is in full keeping with the ethics of the Pythagoreans. They insisted that all instruction must be based on willingness of pupil and teacher, on voluntary rule as well as on voluntary obedience. As Plato saw it, the Pythagorean "way of life" meant no political or group movement; Pythagoras wished to stir the conscience of the individual, and this desire appears vividly in the Oath. If Dr. Edelstein is right or substantially right—and we believe that he has made a very strong case—most of the difficulties and contradictions of this venerable and venerated document fade happily away.

CLIMACTERIC YEARS

It would be amusing to make a list of authors whose names we all know but whose works we have never read. Richardson would be high in the list and Edmund Spenser not very low down; still, curiosity has tempted people not sitting for examinations to try *Clarissa Harlowe*, and a good many have begun the *Faerie Queene*. A name to put very high up is Salmasius. More school-boys than those of Macaulay remember that John Milton had a controversy with Salmasius (Claude de Saumaise), and some of us recollect Dr. Johnson's remark: "As Salmasius reproached Milton with losing his eyes in the quarrel, Milton delighted himself with the belief that he had shortened Salmasius's life, and both perhaps with more malignity than reason."

The year before Salmasius wrote his defence of Charles I he published a dissertation on climacteric years; which, it is safe to say, not even Macaulay's school-boy has read. I possess a copy which once belonged to Sir George Buchanan, F.R.S., given to me by his son the late Sir George Seaton Buchanan. "Climacteric" has still a faintly medical aroma.

¹ *Supplements to the Bulletin of the History of Medicine*. Editor, Henry E. Sigerist. No 1. *The Hippocratic Oath*. Text, Translation, and Interpretation by Ludwig Edelstein. Baltimore: The Johns Hopkins Press, 1943. (51 25: to subscribers to the Bulletin of the History of Medicine, \$1 00)

I think it is now old-fashioned to use the word as a synonym of the menopause, and hardly anybody calls the sixty-third year of life the grand climacteric. I cannot honestly say that I have read every one of the 820 pages of this book, although it has some medical interest it is not primarily a medical book. Indeed, Salmasius is quite clear that the subject of climacterics belongs not to medicine but astrology, and most of the first seven hundred pages are concerned with astrology—viz., what Greek and Roman writers said, and how climacteric years were computed.

Most of us know just as much of the technique of astrology as we can learn from *Guy Mannering*, and I cannot recommend Salmasius as a guide to its mysteries. He was no doubt an extremely learned man, but his arithmetic is weak and his illustrations of working rules inconsistent one with another. Possibly he did not check his arithmetic because the further he went with his studies the stronger became a conviction (expressed, the reader will recall, by Dominic Sampson) that judicial astrology was pure nonsense. Possibly the problem of twins first excited a doubt—he comments on the different fates of Jacob and Esau, who, however, were not identical twins—but, anyhow, his last hundred pages vigorously assail the whole doctrine and do have a medical flavour. He returns more than once to the problem of alcoholism. It is indeed rather hard to see how the importation of wine into what was once a water-drinking country could be allowed for in judicial astronomy. He wants to know what the stars could do about new diseases, and discusses smallpox (that part of his book was annotated by Sir George Buchanan). He also is sarcastic (writing in Latin gave him an advantage in times when sexual perversions were not topics of polite conversation) on the influence of the stars on the variations of homosexuality in different places or in the same place at different times. Indeed, his onslaught on stellar influences is so vigorous that one might think it odd he should give so much attention to what was essentially, in his opinion, so silly. That, however, would be unjust. Salmasius, like his great predecessor Scaliger, wished to know what the Greek and Roman writers had said and believed—whether rightly or wrongly—on all subjects which seemed to them important, and, coming after Scaliger and being intellectually a much smaller man, his harvest of valuable information was inferior.

Johnson said of the controversy between Milton and Salmasius "No man forgets his original trade: the rights of nations, and of kings, sink into questions of grammar, if grammarians discuss them." Salmasius was certainly more interested in grammar—in Johnson's sense—than in the question whether there were any basis in fact not for judicial astrology but for belief in climacterics.

Sir Humphry Rolleston in his *Linacre Lecture (Some Medical Aspects of Old Age, London, 1922)* concluded that "The conception of the climacteric disease is interesting historically only, and it may be agreed that apart from accidents of environment the progress of senescence in healthy men is gradual and ineventful." One must, however, note that the old doctrine did not imply a sudden deterioration, but a change, whether for better or worse. Some men go downhill rapidly after retirement others seem to have taken a new lease of life. Without a large collection of minutely and accurately recorded diaries kept by men from say, the age of 60 to death, we could hardly test the hypothesis. No doubt a diligent student could assemble a goodly number of diaries fulfilling the condition, but the statistician would object that diarists are not a random sample of mankind, so the grand climacteric is likely to remain of antiquarian interest only. M G

HISTORY OF COMPARATIVE ANATOMY

Prof F J Cole of University College, Reading, has furnished zoologists and anatomists of to-day with a delightful retrospect of the older naturalists from the times of Aristotle, Galen, and Pliny to the beginning of the eighteenth century. The interest of readers of this work, *A History of Comparative Anatomy*, is maintained throughout by the variety of aspects from which the subject has been viewed, and by the manner

in which the author has considered the character and work of each individual in accordance with the period in which he lived—e.g., before the old prejudice against the dissection of the human body had been overcome, and "zootomists" were compelled to limit themselves to dissection of apes, dogs, and pigs in order to gain an insight into the anatomy of the human subject, or, at a later period, before the use of the compound microscope and the various methods of injection of vessels and other cavities had been evolved, or before the employment of preservatives such as turpentine or alcohol in the form of brandy or rum. Prof Cole also clearly distinguishes the different lines of approach which inspired the work of the early naturalists. Thus human anatomists, from the sixteenth century onwards, have, in order to understand more fully the mechanism of the body, tended to study the structure of the various organs and systems in relation to their function. Among these may be mentioned Harvey, John Hunter, Malpighi, Perrault, Stenon, Swammerdam, and Tyson, who established the physiomorphological aspect of comparative anatomy, whereas others, apparently inspired by simple curiosity, collected and dissected any material which came to hand, without system or definite object as contrasted with the study from a medical or utilitarian standpoint, such as that which activated the researches of Pasteur and others at a later date. As an example of the collector type of naturalist, F Ruysch of Amsterdam may be cited, an illustration of whose work is shown in Fig 199, a pictorial museum exhibit composed of various emblematical representations grouped in a "grotesque arboreal" fashion on an hexagonal wooden stand—e.g., "a skeleton in extremis, grasping the emblem of insect mortality, the may fly."

The book is well illustrated and the reproductions of many of the original figures show the great exactitude and artistic capacity of some of the early naturalists, or their draughtsmen as evidenced by the drawings of Leonardo da Vinci, Swammerdam, Leeuwenhoek and others. The figures as a whole are most instructive and would have been even more so if the lettering and numbers had been more fully explained either in the legends or in the text. The work concludes with an appendix consisting of biographical notes and a bibliography. It represents a valuable and crucial survey of the history of adult comparative anatomy, which will be a welcome addition to the libraries of all who are interested in the progress of biological science.

Correspondence

Military Psychiatry

SIR.—The letter of Dr B H Shaw on military psychiatry (*B.M.J.* Aug 12, p 222) points out apparent contradictions in the article by Lieut-Col H B Craigie entitled "Two Years Military Psychiatry in the Middle East" (July 22, p 105).

Dr Shaw directs attention to the high proportion of psychotic and neurotic casualties returned to duty with the Middle East Force, and contrasts these figures with Lieut-Col Craigie's statement that such men's "presence constitutes a continued if only potential menace to the morale of the group as a whole." As Consultant in Psychological Medicine to the Director of Medical Services of the Middle East Force during the whole of the period in which fighting took place against the Italians and Germans in the huge area known as the Middle East, I venture to submit a few words of explanation and amplification of Lieut-Col Craigie's remarks.

Evacuation from the Middle East was always a difficult problem even if it was desirable for most cases of neurosis. Man power was a serious matter also, and use was made of every available soldier. The policy of the Psychiatric Services therefore was always directed to treatment and rehabilitation by all possible means followed by a careful estimation of the potentialities of each invalid on recovery. The result was that a great many such recovered men were regraded in medical category and were replaced somewhere in the military machine. It may well be that Dr Shaw has pictured these recoveries returning to combat duties with fighting units. This was not

¹ *A History of Comparative Anatomy from Aristotle to the Eighteenth Century*. By F J Cole (Pp 524, illustrated 30s). London: Macmillan and Co. 1944.

become negative after 3 to 6 weeks, although sometimes persisting much longer. In cirrhosis there is little change from month to month, so that repeated observations help to decide between these two. In arsenical jaundice—i.e., jaundice

TABLE II.—Serum Colloidal Gold Reaction in 319 Cases

	Precipitation Number						Totals	% Pos.
	5	4	3	2	1	0		
Obstructive jaundice	0	0	0	3	0	39	42	7
Infective hepatitis	84	24	22	10	7	11	158	93
Cirrhosis and subacute hepatitis ..	12	0	0	0	0	0	12	100
Arsenical jaundice	5	5	4	6	7	35	62	44
Weil's disease (jaundiced)	0	0	3	2	3	11	19	42
Weil's disease (not jaundiced) ..	0	1	1	1	1	10	14	29
Toxic jaundice	0	0	0	1	0	2	3	
Amyloidosis	0	0	0	1	1	5	7	
Liver abscess	0	0	0	0	0	2	2	

occurring during antisyphilitic treatment—and also in Weil's disease negative results are frequent (about 60%) and make the distinction from biliary obstruction more difficult, but fortunately this is rarely a clinical problem. The rather striking difference between the infective and the arsenical cases has been noted elsewhere (MacLagan, 1944b), and suggests a probable aetiological difference in the two groups. In liver abscess and in amyloidosis results have been mainly negative.

As with most other liver function tests some positive results occur in heart failure, in severe chronic anaemia, and in various acute and chronic infections, of which the following are the most important: glandular fever, atypical pneumonia, infective endocarditis, advanced pulmonary tuberculosis, and rheumatoid arthritis (MacLagan, 1944a). In this group the liver involvement was obviously only an incident in the primary disease, but such conditions might complicate obstructive jaundice, when due allowance would have to be made. In practice they can usually be eliminated without difficulty by other means.

Finally, it should perhaps be emphasized that the results given here are not the same as those obtained with Gray's (1940) original technique, which has been adversely criticized by Mateer *et al.* (1942). The technical details referred to above must be followed exactly if comparable results are to be obtained.

II. Serum Alkaline Phosphatase

This estimation, like the gold reaction, does not test any known function of the liver, and raised values are found in infancy and in a variety of bone diseases. In spite of this the test has been much used in jaundice since Roberts's (1933) observation that the level is usually higher in obstructive than in other types of jaundice. The 136 results in Table III were obtained by the method of King and Armstrong (1934).

TABLE III.—Serum Alkaline Phosphatase in 136 Cases

	Range of Values (Normal 3–13 Units)							Totals
	0–13	14–24	25–35	36–45	46–55	56–80		
Obstructive jaundice	0	3	7	13	11	9	43	
Infective hepatitis	6	35	6	0	0	0	47	
Cirrhosis and subacute hepatitis ..	0	6	3	2	2	1	14	
Arsenical jaundice	8	12	2	0	0	0	22	
Toxic jaundice	1	3	0	0	0	0	4	
Amyloid disease	0	0	2	1	0	0	3	
Liver abscess	0	0	2	0	1	0	3	

It will be seen that the test is of some value in distinguishing biliary obstruction on the one hand—usually over 35 units—from infective hepatitis and arsenical jaundice on the other—usually below 25 units and may be within normal limits. However, 15 of these cases fall into the doubtful range (25–35 units), and 3 of the obstructive cases were below 25 units. This is about the same degree of overlap reported by others (Gutman *et al.*, 1940; Giordano *et al.*, 1939; Higgins *et al.*, 1944). If, however, cirrhosis has to be considered the test is of much less value, as figures over 35 are frequent in this condition. In liver abscess and in amyloid disease a raised phosphatase is often present, and may be the only biochemical indication of disturbed liver metabolism.

III. Galactose Index

This index (MacLagan, 1940) is the sum of the four blood-galactose values at 1/2, 1, 1½, and 2 hours after the oral

administration of 40 g. of the sugar. The estimations were performed mainly on capillary blood as previously described, the results being read from the table given below (see Appendix). This table is based on figures given in the reference cited above and does not involve any alteration in the method. The normal limits, for the galactose index, based on 50 normal subjects, are 0–160 (0–110 for male medical students). The test is contraindicated by nausea or vomiting from any cause.

TABLE IV.—Galactose Index in 145 Cases

	Range of Values (Normal 0–160)							Totals
	0–160	161–200	201–300	301–400	401–500	501–600		
Obstructive jaundice	23	3	7	4	2	0	39	
Infective hepatitis	4	5	15	8	3	1	36	
Cirrhosis and subacute hepatitis ..	0	1	8	2	2	0	13	
Arsenical jaundice	0	1	2	6	1	2	12	
Toxic jaundice	0	0	2	1	1	0	4	
Hyperthyroidism (from MacLagan and Rundle, 1940)	11	7	16	4	3	0	41	

It will be seen from Table IV that the index is nearly always above normal in infective hepatitis, arsenical jaundice, and cirrhosis, but is frequently normal in jaundice due to biliary obstruction. Considerable impairment of function can, however, be demonstrated in certain cases of obstructive jaundice, particularly after the first three weeks, in febrile or cachectic patients, and after repeated attacks of obstruction (MacLagan, 1941). The only normal results in the toxic and infective group were in 4 cases of infective hepatitis in young adults from the Services, a class of patient in which liver function is no doubt above the average. The test is therefore of some value in distinguishing these two groups if interpreted with due regard to clinical data. A normal result in an elderly jaundiced patient is of particular diagnostic value, and has so far been seen only in obstructive jaundice. It is also useful as an extra aid in cases in which the gold and phosphatase tests are equivocal and for assessing the degree of liver damage when present.

The test has also been much used in hyperthyroidism, in which there is impaired tolerance in a high proportion of cases (Althausen *et al.*, 1940; MacLagan and Rundle, 1940; Barnes and King, 1943; and Table IV). Some workers have found it as sensitive as the B.M.R. in diagnosis, although Rundle and I got values decisively above normal in only 75% of our cases; it is agreed that the test is less affected by iodine therapy than is the B.M.R. There is some difference of opinion as to the mechanism involved, since both liver damage and increased intestinal absorption have to be considered. Most recent articles express the view that both factors contribute to the results in hyperthyroidism (Lichtman, 1941; Grauer *et al.*, 1942; Rosenkrantz *et al.*, 1942).

Discussion

It is now generally agreed that a combination of liver function tests yields more information than any one test, and this is particularly true of those described here. Liver function tests are useful in three principal types of case.

1. *Suspected Liver Disease in Non-jaundiced Patients.*—The three tests appear to be sensitive enough to detect cirrhosis, and in common with others they also indicate hepatic involvement in a variety of other diseases such as hyperthyroidism (galactose index), heart failure and various infections (serum colloidal gold reaction), and in liver abscess and amyloidosis (serum alkaline phosphatase). In this group the pigmentary tests—serum bilirubin and urinary urobilin estimations—reach their maximum degree of usefulness and should not be omitted, but they may sometimes be completely negative in cases with known liver damage.

2. *Jaundice of Known Origin.*—The galactose index will reveal liver damage in late biliary obstruction, the other two tests being of no value in this respect. Either the gold reaction or the galactose index may be used to follow the course of a hepatitis, and will often give positive results for some weeks or months after the disappearance of clinical or latent jaundice. In cirrhosis and in subacute hepatitis all three tests have been positive, and the galactose index appeared to have some correlation with clinical severity, so far as could be judged from this small series (13 cases).

3. *Jaundice of Unknown Origin.*—Haemolytic jaundice is usually diagnosed by clinical and haematological methods, and will not be considered here. The way in which these tests can help in the more difficult task of distinguishing obstructive from toxic and

infective jaundice is indicated in Table V, which shows the typical or average results in the types most commonly encountered

TABLE V—Typical Results with 3 Tests in Jaundiced Patients

	Gold	Phosphatase	Galactose Index
Obstructive	Negative	Over 25	Frequently normal
Infective hepatitis	Positive	Under 25	Raised
Cirrhosis and subacute hepatitis	Positive	Raised	Raised
Arsenical	44% pos.	Under 25	Raised
Weil's disease	42% pos.		

The interpretation of the results in these cases must always depend partly upon clinical data and can never be completely rule of thumb. Nevertheless there are many instances in which a slight acquaintance with the history permits an almost certain diagnosis on the basis of the tests. Considering the gold and phosphatase tests first, three particular combinations appear to have diagnostic significance. (A) A negative gold reaction with phosphatase above 35 units suggests biliary obstruction. (B) A positive gold reaction with phosphatase below 25 suggests parenchymatous hepatic disease and absence of biliary obstruction. (C) A strongly positive gold reaction (4 or 5+) has not been seen in obstructive jaundice and appears to be diagnostic with any phosphatase level. In such cases a phosphatase above 35 suggests cirrhosis rather than acute hepatitis.

It will be evident from Table V that the chances of making the distinction are greater in infective hepatitis and cirrhosis than they are in arsenical jaundice and Weil's disease but unfortunately the two latter conditions do not usually present great diagnostic difficulties. When the gold reaction is positive possible complicating diseases must be considered, but these rarely cause serious trouble in interpretation.

The constancy of these findings is illustrated in Table VI which includes all jaundiced patients on whom both tests were

TABLE VI—Combination of Two Tests in 100 Jaundiced Patients

	1	2	3	4	Totals
Gold Phosphatase	Negative Over 35	Negative Under 25	Positive Over 25	Positive Under 25	
Obstructive jaundice ¹	22	9	1 (1+)	0	32
Infective hepatitis	0	7	1 (5+)	28	36
Cirrhosis and subacute hepatitis ²	0	0	4 (All 5-)	6	10
Arsenical jaundice	0	6	1 (5-)	12	19
Toxic jaundice ³	0	2	0	1	3
Totals	22	24	7	47	100

¹ Due to pancreatic carcinoma in 14, gall stones in 9, hepatic metastases in 6, and other causes in 3. Diagnosis established by re-excision in 15, laparotomy in 1, and by other methods in 2.

² Diagnosis established by necropsy in 5 cases, biopsy in 2 and clinically in 3.

³ Due to T. T. in 2 cases and to sulphapyridine in 1.

⁴ Figures in brackets indicate strength of gold reaction.

done. It will be seen that out of these 100 cases 75 fall into group A, B, or C (columns 1, 3, and 4) and in all of these the findings were in keeping with the final diagnosis. The galactose test was confirmatory in 26, omitted in 41, and atypical in 8. The atypical galactose tests were 4 cases of biliary obstruction with secondary liver damage and the 4 cases of infective hepatitis in young adults referred to above.

In the remaining 25 cases (column 2 and one case in column 3) the results did not always give a definite answer, but in some instances the galactose test provided further information. They may be classified as follows: (1) Three cases of obstructive jaundice with negative gold reactions and phosphatases of 16, 25 and 29, and galactose indices of 118, 126, and 114 respectively. In view of the ages of the patients—72, 62, and 40—the normal galactose tests here were felt to be strongly in favour of what proved to be the correct diagnosis. (2) A group of 22 cases with negative or weakly positive gold reactions in which the findings were conflicting and of little diagnostic value. These consist mainly of obstructive and arsenical jaundice but include some cases of infective hepatitis and toxic jaundice. The galactose test was omitted in 18 of these and in some it would probably have helped. In two of the obstructive cases a later repetition of the tests showed a rise of the phosphatase to a diagnostic level.

The final assessment of the three tests in these 100 jaundiced patients is therefore that the distinction between biliary obstruction

and generalized liver disease could be made in at least 78, which include about the same proportion of the obstructive and of the non obstructive cases. It is not, of course, suggested that these rules of interpretation will be infallible but since no exception to them has been observed in this series they appear to be reliable enough to form a useful diagnostic guide.

As a matter of practical convenience it is easier to do the gold and phosphatase tests first and to reserve the galactose for cases in which the first two are atypical or in which the degree of liver damage is of interest. The galactose index has, however, a special place in the investigation of hyperthyroidism.

Summary

The clinical value of laboratory tests in the diagnosis of liver disease has been reviewed with special reference to the serum colloidal gold reaction (319 cases), the serum alkaline phosphatase (136 cases), and the galactose index (147 cases).

The first two tests taken together, often give valuable diagnostic information when considered in conjunction with clinical data. A jaundiced patient with a negative gold reaction and a phosphatase above 35 King Armstrong units probably has biliary obstruction, one with a positive gold reaction and a phosphatase below 25 units probably has not. A 4 or 5- gold reaction is against biliary obstruction whatever the phosphatase level.

The galactose index is useful as a confirmatory test in special cases and for assessing the degree of liver damage when present. It is also of value in the diagnosis of hyperthyroidism.

The results given indicate that out of 100 jaundiced patients the distinction between biliary obstruction and generalized liver-disease could be made in 75 cases with the gold and phosphatase tests, and in a still higher proportion if the galactose index was included.

I am much indebted to the medical staff of the Staines County Hospital and of Sector 7 for permission to investigate their patients, and to Prof. A. D. Gardner, Dr. E. N. Allott, Dr. A. J. Amor, Major J. Marshall and the Middlesex County Medical Society for various sera.

ARTIFICIAL RESPIRATION

THE NEED FOR A GREATLY INCREASED RATE IN ASPHYXIA

BY

P. R. TINGLEY, M.B., Ch.B.

The rate in all methods and teachings of artificial respiration varies between 12 and 18 times a minute. This rate has persisted to the present time, unaltered and unchallenged for all conditions and requirements. The purpose of this article is simply to demonstrate the obvious error or oversight in the application of *all methods* of artificial respiration to cases of asphyxia without at the same time considering the greatly increased respiratory requirements existing in asphyxia and making some attempt to meet these requirements. (The word "asphyxia" is used throughout as being synonymous with "suffocation" and "cyanosis.")

All cases for which artificial respiration is required may be considered to fall into two main groups:—Group 1: cases without asphyxia—e.g., under anaesthesia, from electric shock, etc.; Group 2: cases with asphyxia—e.g., suffocation from drowning, from lack of air (buried in bomb debris), from smoke, gases, etc. Any Group 1 case, if untreated, quickly becomes a Group 2 case.

Artificial respiration done at the usual rate of 15 times a minute is adequate and excellent for Group 1 cases, as the respiratory requirements are approximately the same as in natural respiration at rest; but the same rate is quite inadequate to deal satisfactorily with Group 2 cases of asphyxia, in which the respiratory requirements are very much greater. The body not only provides a natural respiration at rest—namely, a tidal breath every four seconds—but also provides it for all normal degrees of exercise and asphyxia whenever they arise in daily life. This natural respiration in asphyxia makes use not only of tidal but also of full complementary breathing at whatever increased rate may be required to deal with existing needs.

The truth of these statements can very easily be demonstrated by simply holding the breath as long as possible and then, on the resumption of breathing, noting the volume and rate of the very necessary respirations. It will be found that slow tidal breathing is most inadequate, if not frankly impossible—and this from a very mild degree of asphyxia. Now consider the deeply asphyxiated person. He must certainly have far greater respiratory requirements, for he has passed more milestones along the road to death; he has lost consciousness, his respiratory centre has ceased to function—only his heart clings stubbornly, though precariously, to life. He is metaphorically crying aloud for air—and is in actual fact dying for want of it. Obviously his respiratory requirements cannot be adequately

the volume or the rate. It may be assumed that each method of artificial respiration at present in use provides the greatest exchange of air possible by that method, so that only by increasing the rate can any greatly increased respiration be obtained. Fortunately, the rate can be raised in all methods with little effort, with no loss in efficiency, and with great increase of the total respiratory exchanges.

It is convenient and correct to consider the increasing depths of asphyxia as being of three degrees: Degree 1, up to loss of consciousness; Degree 2, up to cessation of respiration; Degree 3, up to final heart failure. It should be realized that it is only in Degree 1 that actual experiments on the state of asphyxia can be carried out, for the deeper degrees of asphyxia occur only accidentally and not under circumstances suitable for experimenting; while it is not practicable that any such asphyxia should be produced "artificially by force" for experimental purposes. It is, however, quite practicable to produce varying depths of Degree 1 asphyxia at will, and without danger, by simply holding the breath for varying lengths of time. It is from experiments in such self-administered asphyxia that we are obliged to gain our knowledge of the manner in which asphyxia may be relieved by varying amounts and rates of respiration.

Experiments in Asphyxia

Each experiment is done in the sitting position, and is started by taking a full, free complementary breath (without forcing inspiration to the utmost) and holding the breath for various stated periods. At least five minutes of natural respiration at rest is enforced before each experiment.

In these recorded experiments a subject has been chosen with sufficient determination to hold his breath for long periods, and of sufficient integrity to report the times at which "the pulse commences to be heard" on holding the breath, and, on resuming respiration, the times at which "the pulse ceases to be heard" and the "acute discomfort ceases." This latter somewhat arbitrary time is that at which one no longer has "fight for more air," though deep rapid breathing may continue for some minutes.

The tidal respiration used in Series 2 has been judged by the subject to be the best of his ability. It is quite feasible for the subject (by conscious control) to breathe an approximately similar amount to the tidal at any time or rate required. That this amount should be exactly the tidal is, of course, unlikely, but any respiratory experiment on the conscious subject is open to error of the "human element," and in these, even though the results were affected thereby very considerably, the same fundamental conclusions could and would be drawn.

Series 1 experiments (see Table) shows results of varying degrees of asphyxia on the natural uncontrolled respiration. As the asphyxia becomes deeper, though the respiratory exchanges are greater the recovery is slower. Asphyxia from only two minutes' stoppage of respiration (Experiment 3) causes the volume of each respiration to be increased at least twice, and the rate to be increased four times. Thus the total volume of air exchanged naturally after only

Experiments in Asphyxia

Experiment No.	Time Breath held (Seconds)	Ear Pulse heard (Seconds)	Type of Respiration used	Rate of Respiration	Ear Pulse ceased (Seconds)	Time taken to be Free of Discomfort (Seconds)	Remarks
Series 1 1	60		Natural	6 in 10 secs.		8	Tidal plus complementary breathing used naturally without control. Volume of each respiration increased to full in Exp. 1, with marked increase in rate also. Rate further increased to as fast as possible in Exp. 4
2	90		"	9 " 10 "		10	
3	120	20	"	12 " 12 "	8	14	
4	150	50	"	30 " 20 "	15	20	
Series 2 5	120	20	Controlled tidal	1 in 4 secs.	Constant	Discomfort increased	Very difficult; asphyxia growing worse all the time. By great effort experiment continued for 40 secs., when will-power dulled and natural respiration reasserted itself Relief definite but very slow Relief much improved over Exp. 6 Practically as good relief as in Exp. 3
6	120	20	"	1 " 2 "	45	c. 60	
7	120	20	"	1 " 1 sec.	15	c. 30	
8	120	20	Forced rapid tidal	2 " 1 "	10	15	
9	60		Controlled tidal	1 in 4 secs.		c. 60	Relief definite but very slow

met by a tidal breath once in four seconds. Yet that is the manner in which it is being administered to-day to the deeply asphyxiated.

On the truth of these simple and obvious facts, which have never before been applied practically to this vital need, I base my claim for the necessity for providing increased respiration in asphyxia. This increase can be obtained only by raising

a moderate Degree 1 asphyxia is at least eight times the total volume exchanged naturally at rest for the same unit of time. (The total volume exchanged by any artificial method at present is seldom much greater than the total volume exchanged naturally at rest.)

Series 2 experiments show the effect on a constant degree of asphyxia obtained by altering only the rate—the volume remaining tidal throughout. Exp. 5 shows that the rate of 1 in 4 seconds provides insufficient respiratory exchange to relieve this particular

degree of asphyxia, and the experiment had to be broken off because of increasing asphyxia. Exp. 6 shows that by increasing the rate to 1 in 2 seconds the relief is definite but very slow. Exp. 7 shows that by increasing the rate to 1 in 1 second the relief is much improved. Exp. 8 shows that by further increasing the rate to 1 in 1 second (in the same manner as a dog pants) the relief is almost as good as by natural breathing in Exp. 3. (This rate of 1 in 1 second is not practicable artificially, but it shows that there is no effective limit to the practical increase in rate.) Exp. 9 shows that tidal breathing 1 in 4 seconds may relieve a very mild asphyxia, but fails to relieve a deeper asphyxia (compare Exp. 5).

Conclusions from Experiments in Degree 1 Asphyxia

1. The deeper the asphyxia the greater the respiratory requirement.
2. In any asphyxia that needs artificial respiration the respiratory requirement must be *greatly in excess of eight times* the normal resting requirement.
3. In the deeper degrees of asphyxia a greater respiratory exchange than in the lesser degrees is required to give an appreciable relief.
4. The total volume of air exchanged in a given time largely determines the extent of relief from asphyxia.
5. The faster the rate of tidal respiration the greater the relief from asphyxia.

Discussion

The above conclusions are undoubtedly true in Degree 1 asphyxia. The respiratory requirements of Degree 3 are essentially the same in quality as in Degree 1, and vary only in quantity. Degree 3 asphyxia should therefore respond to increased respiratory exchange in much the same manner as does Degree 1—*provided the circulation is adequate to take up and distribute the extra oxygen made available.*

The circulation, which remains fairly constant in Degree 1, becomes gradually more and more enfeebled and inadequate throughout Degree 3. It must therefore be fully realized that in Degree 3 asphyxia the state of the circulation may play as great a part in determining the extent of relief from asphyxia as the respiratory exchanges do. They are very closely inter-related. The circulation is now directly dependent on the respiration. The only possible way to improve the circulation is to ensure that a fully adequate supply of oxygen is available in the lungs, to be transported to the needy cardiac muscle. In brief, in a hypothetical case, if the circulation is still fairly adequate (the radial pulse being discernible) the recovery obviously must be much quickened by using a greatly increased rate. If, however, owing to long asphyxia, the heart is failing fast and the circulation is hopelessly inadequate, so that a tidal breath once in four seconds already provides more oxygen than can be taken up by the greatly depleted pulmonary circulation, there is nothing to be gained by increasing the respirations, as the patient would seem to be doomed, whatever may be done. It is, however, in the border-line case, in which the circulation is able to take up all the oxygen available at the usual rate and still be wanting more, that the greatest benefit will result from an increased rate. For in this case of deep asphyxia with failing circulation the tidal breath once in four seconds is inadequate to clear up the deep existing cyanosis and to maintain in addition the heart and body requirements (as shown by Exp. 5). Such cases have no doubt provided most of the recorded failures. By increasing the rate, and providing about four times as much air, not only do we give the patient a "much better chance," but it is not unreasonable to assume that some such cases, previously "on the down grade" at the usual rate, would revive with the increased rate. It must further be borne in mind that the blood in such a case is almost completely devoid of oxygen, and therefore can take up far more of it, volume for volume, than the blood in Degree 1, which can take up eight times the normal amount very readily. Thus, even though the flow of blood through the lungs may be very poor indeed, it is quite possible that all the oxygen available from tidal breaths every four seconds may be fully taken up by this deeply cyanotic blood, which then is left "hungry" for more oxygen. Therefore, it is essential to provide all the respiratory exchanges possible if every case is to have its best chance of recovery. It may, at least, confidently be stated that an increased rate can do no harm in any case, and must in many instances do much good.

It has been shown (Exp. 8) that the effectiveness of increasing the rate of tidal breathing continues beyond any practicable limit—provided the circulation is adequate; and as any hopelessly inadequate circulation cannot be recognized on examination, the only safe rule to adopt in all cases is to employ as fast a rate as may be efficiently possible.

It is not essential to discuss the relative parts played in asphyxia by the diminishing oxygen supply and the increasing carbon dioxide, or the varying effects of asphyxia on the different nerve cells or its effect on the cardiac muscle. All such considerations are of little importance from the practical point of view, because all manifestations of asphyxia, of whatever nature or degree, are the direct result of respiratory failure, and can only be improved by providing adequate respiratory exchanges.

The Rate Suggested

In every method the present rate is slow. Four seconds is a long time when applied to one respiratory cycle. Indeed, in most methods it has been necessary to include a pause of one to two seconds in each cycle in order to keep the rate down to the so-called normal. In Schäfer's the interval is at the end of inspiration; in Eve's it is at the end of expiration. There has been considerable discussion as to the proper place in the cycle for this interval and the proper timing. My only comment is to draw attention to the undoubted fact that in natural respiration for even mild degrees of asphyxia there is no time for a pause at all at any period, inspiration and expiration being as quick as possible, and following each other as rapidly as possible. In all artificial methods the same manner of respiration should be provided.

In Schäfer's method it is difficult to occupy fully even three seconds with the actual movements necessary for one cycle. It is, in fact, much easier, and just as effective, to do all the movements in two seconds instead of three. The second so saved could be utilized, along with the second previously set aside for an interval, by providing the two seconds necessary for another cycle. Thus the rate may be doubled, without any undue effort at all, by merely substituting an easier rate of 30 times a minute. Now, in the interest of the dying patient some real physical effort should be made, and under most conditions this rate of 30 times a minute can be doubled. It is not difficult to do Schäfer's method at a rate of 60 times a minute without any loss of volume per respiration. Under few circumstances, with an adult operator, should it be necessary to let the rate drop very much below 60.

Silvester's method, because of the nature of the movements necessary, takes more time to perform than Schäfer's, and a rate of about 45 times a minute would seem to be the efficient maximum. My limited experience of Eve's method does not permit me to suggest the most suitable rate, but the same rule holds true—"as fast as possible consistent with no sacrifice in volume"—and I have little doubt that the efficient rate of rocking could be at least doubled, and probably much further increased.

Considering the number of cases of asphyxia occurring on land and sea under war conditions, the early adoption of this principle, and its teaching to all appropriate personnel, cannot be too strongly urged.

Conclusion

The respiratory requirements are so great in all cases of asphyxia which require artificial respiration that, in such cases, the adoption in all methods of as fast a rate as possible, consistent with efficiency, must result in the quicker resuscitation of the patient, thereby enhancing the chances of life.

Holler (*Die Chemie*, 1944, 57, 14; *Dtsch. Gesell. inn. Med.*, Oct., 1943) classifies the causes of liver damage on a clinical basis as follows: (1) Endocrine disturbances: hyperthyroidism, diabetes mellitus, pregnancy. (2) Chemical poisons: phosphorus, arsenic, hypnotics, etc. (3) Food toxins as in "meat poisoning." (4) Spirochaetal diseases: Weil's disease, marsh fever, secondary syphilis. (5) Drugs: atophan, salvarsan, evipan, *Felix mas.* (6) Infections: jaundice in pneumonia, sepsis, rheumatism, diphtheria, scarlet fever, epidemic meningitis, etc. (7) Infections with monocytic or monolymphocytic reaction (Pfeiffer's glandular fever, epidemic hepatitis). Holler regards as specially characteristic of epidemic hepatitis the appearance of numerous monocytes in the blood; this he interprets as "a mobilization" of the reticular endothelial system.

PSYCHIATRY IN DETENTION

BY

R. R. PREWER, M.R.C.S., L.R.C.P., D.E.M.

Surg. Lieut.-Cmdr., R.N.V.R.

The report of the Oliver Committee, recently published, has drawn the attention of the public to the detention system used in the armed Forces, with special emphasis on the medical arrangements. In civil life the association of mental abnormality with delinquency is notoriously close, and it is not surprising that a similar association is discovered among Service offenders. It was thought to be of interest, therefore, to discuss the scope of psychiatry in detention establishments and briefly to describe the various types of abnormality which may be encountered there. Owing to the necessity for economy in medical manpower, it is impossible for us to copy the American practice of appointing a whole-time psychiatrist to each of the larger detention establishments; accordingly, it is incumbent upon the medical officer himself to utilize to the full such opportunities for psychiatric investigation as come his way.

Diagnosis

A small proportion of the offenders received in Naval detention quarters have already been reported on by the psychiatrist at their depot before sentence, and yet others have earlier psychiatric reports included among their medical documents; but the majority, coming as they do from isolated ships and bases, have not previously been assessed from the psychiatric angle. The field, then, is large and the time all too short for undertaking a thorough investigation of every case. A compromise must be reached, and it is our custom here to interview each offender alone as soon as possible after admission (often on the same day) and to discover as rapidly as possible the salient facts relating to his health, previous Service record, early environment, school and work histories, and hereditary influences. These facts are recorded on a special form and filed for reference. It is possible in this way to gain a general impression of the mentality of each offender in less than a quarter of an hour; and though it is of course impossible to form a correct opinion in every case, there is still the whole sentence in which to review hasty and ill-judged conclusions. Nowhere in the Service is the medical officer in a better position to observe his charges, and though the atmosphere is an artificial one, it is certainly less artificial than that of a hospital ward. He can watch the men through the whole of each day's routine, at drill and physical training, at school instruction, at industrial work, and even engaged in such necessary tasks as washing clothes or peeling potatoes. In the absence of difficulty or doubt he can confer with the instructors and officers, and more especially with the chaplain, who has his own records and is in touch with the home environment of the offender in many cases. Where it appears that we are dealing with an abnormal case, however, a more extended examination is necessary, and further interviews or even a period under observation in the sick-bay may be called for. The results obtained by these various methods are utilized in two ways. Directly, to advise regarding the immediate treatment of any particular individual and modification of the detention routine if deemed necessary; and indirectly, in bringing him to the notice of his depot psychiatrist shortly before the expiration of his sentence. In grossly abnormal cases, however, direct and immediate discharge to hospital for invaliding or specialized treatment is our invariable rule.

Treatment

The uncomplicated and regular life, hard exercise in the open air, generous hours for sleep, and the deprivation of alcohol and tobacco, all combine to improve the general physical condition of the average offender during his sentence, and, incidentally, to soothe and resolve the conflicts in his mind. Ocular demonstration is forthcoming in all but a small group of psychopaths, and the medical officer can observe how, in a few weeks, the sullen and resentful new arrival changes into a more placid and more co-operative individual. In the abnormal cases this process is generally obvious, and all that is required of the M.O. is a little moral support for the weak,

reassurance and sedatives for the anxious in their earlier stages, and a certain allowance, tempered with firmness, for the idiosyncrasies of the psychopathic personality. The scope of psychotherapy in detention is strictly limited; for the medical officer is essentially an official in the eyes of the offender, just another link in the chain of Naval discipline. A similar disadvantage in the case of the prison medical officer was remarked upon by the Departmental Committee on Persistent Offenders in 1932. Moreover, the ordinary medical officer has other duties to perform, and even the time of the offender is limited; for so finely is his day adjusted for him that a long treatment session might deprive him of a bath or school instruction or necessary exercise. We have on occasion used narco-analysis to clear up periods of amnesia and other gross hysterical phenomena, but as a rule no advanced treatment is attempted. East and Hubert (1939) draw attention to the abuses which may creep in when the offender realizes that psychotherapy has possibilities for extorting concessions from the authorities in civil prisons; and the average Naval offender would not be slow to realize also that attendance for regular treatment is "a good wicket," and infinitely better than drilling or doing manual tasks. It is preferable to cart over those who can wait for the treatment of psychiatrists in depot; and those cases that cannot wait are transferred, as already stated, to hospital.

Results of 1,000 Investigations

The following is a brief outline of the findings in 1,000 cases admitted to this establishment for the first time. Of these 773 appeared to be well adjusted to life in general and a Service environment in particular; their offences were occasionally due to pressure of external circumstances, but the great majority were due to causes well within the control of the individual. As a rule these men had gone into delinquency with their eyes open, took their punishment as a matter of course, and went back to duty afterwards duly deterred for the future. On the other hand, 227 were found to be suffering from conditions as set out in the following table:

Organic cerebral causes	3	Mental defectives	6
Epilepsy	5	Mentally retarded	59
Schizophrenia	2	Anxiety-hysteria	31
Schizoid personality	15	Alcoholism	13
Depression	1	Homosexuality	3
Cycloid personality	2	Psychopathic personality	87

44 cases in the abnormal group gave a family history of epilepsy—a percentage for the group of 19.4; similarly, 46 (5.9%) of the normal group gave a similar history.

44 (19.4%) of the abnormal cases gave a family history of psychosis, severe neurosis, or certifiable mental deficiency; 54 (6.9%) of the normal cases gave similar histories.

83 (36.6%) of the abnormal cases admitted to at least one conviction before a civil court on a serious charge and 131 (16.9%) of the normal group made similar admissions.

It is significant that nearly all the thousand cases in this series came from large towns, especially Glasgow, London, Liverpool, and Tyneside; that the majority were of low general intelligence and education, and had had no hobby, study, sport, or intellectual interest before they joined the Service. They included a large proportion of unskilled workers, and were almost all from the non-technical branches of the Navy. It is thus evident that education and mechanical ability are strong factors in preventing delinquency in Service personnel.

The Abnormal Groups

Organic Cerebral Causes.—No final decision was reached about the 3 cases in this category. Two had strong presumptive evidence of severe head injuries in civil life, and the third was an ex-sparring partner who had been knocked out a number of times in boxing booths. All three were liable to become excited and confused on small doses of alcohol, but otherwise there was little connexion between their disabilities and their offences.

Epilepsy.—These 5 cases, of idiopathic type, were sent to hospital for invaliding. All five had suppressed their history when before a National Service Board. It is unlikely that their epilepsy bore any relation to their offences, which were all for absence without leave. Only one was seen to have a fit while under sentence.

Schizophrenia.—Only 2 incipient cases of this disorder were seen. One expressed the hope, in an apologetic manner; that he would not be mistaken for a German, and complained that others had been rapping messages about him on the walls; this was on the day of admission, and no further abnormalities were discovered during the rest of his sentence. On discharge he was referred to his depot psychiatrist for observation, and subsequently developed further delusions and was removed to hospital. The other patient drew attention to himself by acting strangely in detention, hiding under his bed, laughing at punishment, and appearing faintly amused at everything; he was sent to hospital, and was subsequently invalided as a schizophrenic.

Schizoid Personality.—These offenders were all above the average in intelligence, said they had never made friends, preferred their own company, and could not get on in the Service because of their inability to live at close quarters with large numbers of other men. They all admitted to over-indulgence in fantasy, and rather enjoyed the solitude of their cells, where they were free from interruption.

Depression.—Only one case of pure depression was seen—of a reactive type. It appears that this man's offence was directly related to his mental state, and he was discharged to hospital. He left hospital much improved, and continued under the care of his depot psychiatrist.

Cycloid Personality.—The swing of mood was abnormally evident in both these cases and justified their position under this category. These people are apt either to cause trouble through disregard of all orders when elated or to wander off and remain absent when depressed. Neither case approached a certifiable degree of abnormality.

Mental Deficiency.—This has become very rare in the Services since the introduction of routine intelligence tests, but occasionally a case appears in detention, having joined before the tests came into operation. Curran and Guttman (1943) draw attention to the low standard of intelligence required for the performance of useful manual work in the Navy, and it is remarkable that men with mental ages of 8 or 9 frequently get along very well doing simple tasks and lead quite happy lives. On the other hand, others have been called up and have reacted to a strange and perhaps unfriendly environment by persistently deserting. Such cases are invalided as soon as they are spotted, but in a vast organization it is not surprising that an occasional defective goes unnoticed for some time. The following case is an example.

Case 1.—Stoker aged 25. Came from a good home, but was always afraid of animals and loud noises; he never got beyond Standard IV at school, and only owed this advancement to his age: while his fellows were at lessons he used to be told off to dig the garden. He then got a job in a small factory near his home, and performed a very simple task for nine years to the satisfaction of his employers. Called up early in the war, he went to sea in a destroyer, where he was terrified because of the noise of the engines; he was unable to learn the intricacies of his new duties. He then began to absent himself on every possible occasion, and served three short sentences in a civil prison. On admission here he stated that his sister was in an epileptic colony and that an aunt had committed suicide. He complained of pain in the back of the head of a "thumping" character, was afraid of being in a cell, and longed to get home; it appears that his wife looked after him like a child. He had never had a fit, but had had one short loss of memory. His M.A. was 7. He was immediately discharged to hospital for invaliding.

Mental Retardation.—This is often accompanied by other abnormalities, such as anxiety-hysteria and psychopathic personality, but all cases of backwardness encountered in this series are shown as such. Their mental ages varied from 8 to 11, though the higher figures predominated. These men came from families in which certifiable deficiency was not uncommon, never got beyond the lowest standards at school, and then drifted from job to job until they were able to find employment which did not require intelligent thought. In the Service they find instruction hard to follow, soon lose interest, waste their pay, and as often as not drink and smoke more than is good for them; many are habitual leave-breakers—more often from lack of imagination than wilful disobedience. Placed under strict supervision on discharge, they generally produce good work of a simple nature, and invaliding is only very rarely recommended.

Anxiety-hysteria.—In common with other recent writers I make no attempt to discriminate the two conditions; nearly all in this series showed both anxiety and hysterical symptoms. The Naval aspects of anxiety states and hysteria have been most thoroughly dealt with by others, and it is not proposed to discuss them further here. Acute cases of anxiety are very rare in detention, though chronic cases are not uncommon. A certain type of offender is ashamed of his fears, and fights shy of the medical officer both before and after his offence: unless he shows objective signs of anxiety, he is liable to escape detection until he appears in detention. Of hysterical manifestations, the fugue has the greatest possibilities from the point of view of delinquency, but such cases have generally received psychiatric investigation before sentence. I have dealt with hysterical reactions to punishment elsewhere. Typical mixed states are apt to be deceptive, but the following is an example:

Case 2.—A.B. aged 24. Complained on admission of "weakness, faintness, pains in the neck and chest, and a lump in the throat." He stated that a brother and a cousin were "nervous," and that he himself had had nocturnal enuresis until the age of 10. He never got beyond Standard V at school, but then worked fairly steadily for five years in a linen-mill and on a farm. After some months of unemployment he joined the Navy, about a year before the war. He got along well enough at first, but after the start of hostilities began to have strange feelings in his chest, and, when the medical officer could find nothing wrong, presumed that he had some unknown disease. He felt so unwell and inadequate that he twice absented himself from duty. On examination he showed objective evidence of anxiety, had a classical hysterical cough, but revealed no other sign of disease. He was put to bed on sedatives, and an attempt was made to investigate his condition, but he rapidly became more distressed in this environment and was discharged to hospital for invaliding.

Chronic Alcoholism.—The 13 men placed in this group had minor disorders which might have justified their inclusion in other categories, but their offences were directly due to their heavy drinking, and their behaviour when free from its influence was normal enough. Under punishment they proved amenable to discipline, and it was clear that if kept at sea, where there is no alcohol except the daily tot of rum, they would give excellent service. On shore leave, however, they were liable to degenerate into insubordinate, quarrelsome, and violent ruffians, more than one was prepared to steal to satisfy his craving. Two appeared to be typical though mild cases of dipsomania. A large proportion of the 1,000 patients claimed that their offences were brought about by alcohol, which they seemed to consider absolved them from all blame, but only the 13 quoted here satisfied one that drink was the primary factor. To add point to the necessity for placing these men beyond the immediate reach of temptation on discharge, one man seen in detention (not included in this series) had been under certificate in a mental hospital before entry, and reference to his records showed that this was directly due to chronic alcoholism.

Homosexuality.—Surprisingly few cases of this were seen, though the possibility was always remembered. All 3 had been investigated elsewhere, had most unsatisfactory personalities on other counts, and one at least had had a breakdown for a long period before the war. They were all discharged from the Service at the conclusion of their sentences, so that medical disposal was not required.

Psychopathy.—This term is unpopular with many authorities, but, restricted to the use defined below, I think that it is justifiable. It is necessary to have some generic term for that large mass of offenders who are markedly abnormal and yet cannot be included under other categories; the term "mentally inefficient" does not appear adequate, as their mentalities are efficient enough when necessary, and some verge on the brilliant within narrow limits. They all show one marked feature in common—emotional instability; it pervades their whole lives. They quarrel with their parents, wives, school-mates, fellow workers, and employers; they shift about from job to job, always hoping for something more congenial, less arduous, and more remunerative. "I can never settle to anything for long" and "I could not get interested in my work" are common remarks from these people. They often throw themselves out of work, remain unemployed for long periods, or wander about the country in an aimless fashion. They certainly do not lack

courage. In the Navy, they resent all discipline, shirk all responsibility, and squander their pay in a reckless fashion. A typical reaction was that of a rating who deserted to pay out his wife for some petty quarrel: "I knew she would lose her money while I was adrift," he said. They are drawn from all classes of society, and some of them have ruined excellent opportunities in early life by refusing to stick to anything. Many have been in approved schools, Borstal, or prison—some in all three; a few of them are habitual criminals, having taken to crime as a livelihood; but the majority have not enough stability even for that. It is not surprising that these men, more especially those of the aggressive type, appear in detention again and again, for violence, insubordination, and absence without leave. Under the transient stress of active service they tend to show up surprisingly well. It is not contended that crime is due to some strange disease, of which the psychopathic personality is one aspect: that conception has been abandoned by modern criminologists. On the other hand, it is significant that a very large proportion of civil and Service delinquency appears in those who have pronounced emotional instability. Such cases do not require hospital treatment or invaliding, and I have little faith in psychotherapy in these conditions. No satisfactory solution has been evolved in this country to deal with grossly psychopathic offenders, though special institutions for treating them were included among the measures in the Criminal Justice Bill of 1938. So far as Service delinquents are concerned, an attitude of understanding firmness, combined with careful placing on discharge from detention, is all that can be attempted at the present moment. The American system of heating the punitive furnace seven times for the psychopath does not appear attractive; but, in any case, the American Forces have the advantage over us of accepting no ex-criminals for enlistment. Many and interesting cases might be quoted from our experiences with psychopaths, but the following is an example of the problem which confronts us:

Case 3.—Stoker aged 45. Came from a poor home, but had no family history of crime or mental disorder. He came under the notice of the police at an early age and spent six years in an approved school. Later, he alternated for many years between the Army (which he entered three times, being three times discharged as incorrigible), the building trade (where he rose to be a foreman), and prison. He claimed to have spent ten years all told in prison, sometimes for burglary and once for robbery with violence. His face still showed the marks of razor-wounds received in racecourse gang-fights. At the outbreak of war he volunteered for the Navy without considering what that might entail; he soon found the life too arduous, and, without ever setting foot on a ship, disappeared. Five times he repeated this conduct, giving trivial and absurd excuses on each occasion. On examination he was the typical "old cheerful, plausible, and apparently friendly. His attitude under sentence varied from a fawning subservience to truculence and open hostility. His general educational level was fair and his intelligence average. His disposal might have caused a serious problem, but he was found to have a high blood pressure, a trace of albumin in his urine, and his retinal vessels showed arteriosclerotic changes. At the conclusion of his sentence he was invalided on account of hyperpiesis.

Comparison with Civil Delinquents

It is hard to find an exact parallel between Service and civil delinquents, as so much Service "crime" is of a purely technical nature. A man may have no wish to be considered abnormal, and yet fail to see the necessity for returning when his leave is up or for staying awake on watch. Civil crimes are usually those of commission, Service offences of omission.

	Civil Prisoners	Service Offenders
Family history of epilepsy	4.8%	10.0%
Family history of insanity, neurosis, or mental deficiency	10.9%	9.6%
Psychosis	7.5%	0.2%
Defective	3.3%	0.6%
Backward	14.1%	5.9%
Epileptics	5.5%	0.5%

The only comparable set of figures with which I am acquainted is that of East (1942) in his investigation of 4,000 young delinquents at Wormwood Scrubs; his cases varied in age between 16 and 20. The present series deals with a rather

higher age group, varying between the extremes of 17 and 46 though the average age was 23½.

With regard to the above comparison, it must be remembered that civil prisons must take all comers, whereas the armed Forces impose a considerable degree of selection on their intake. It will be seen, however, that the same kind of psychiatric investigation is required, whether in a civil or Service environment, when dealing with gross or repeated forms of delinquency.

Summary

The possibilities of psychiatric investigation and treatment of delinquents in Service detention establishments are discussed. It is suggested that the role of the ordinary medical officer is that of diagnosis, leaving treatment to be carried out elsewhere after discharge from detention.

It is shown that of a series of 1,000 Naval offenders who were briefly investigated 22.7% proved to be mentally abnormal.

The various types of abnormality seen in detention are briefly described, with a suggestion as to the bearing that those abnormalities have in promoting offences. A comparison between civil and Service delinquency is added.

PROTEOLYSED BEEF IN THE TREATMENT OF COELIAC DISEASE

BY

A. C. ADAMSON, M.P.S.

Senior Pharmacist, Southend General Hospital

AND

DAVID LEWES, B.M., M.R.C.P.

Medical Registrar, Southend General Hospital

The importance of a diet rich in protein is well recognized in the treatment of coeliac disease and related conditions characterized by chronic jejuno-ileal insufficiency. The period of maximum incidence of coeliac disease is between the first and third years. The protein requirements per unit of body weight at this time of life are approximately twice that of an adult, while the ability to digest protein foods in infancy has an upper limit proportionately lower than in the adult. In coeliac disease gross impairment of the powers of absorption of the products of digestion, relating particularly to those of fat and protein, is superadded to the requirements and limitations already mentioned. These considerations, together with the apparent failure of any previous form of treatment to effect improvement in one of the cases reported, suggested to one of us (A. C. A.) the possibility of ensuring a high protein intake by the oral administration of proteolysed beef. The suggestion was therefore adopted, with encouraging results.

Our purpose is to present this method of treating coeliac disease. It should be made clear from the beginning that the line of therapy is based on the desideratum of a high protein diet in coeliac disease, and is on no account to be regarded as a substitute for or a replacement of the other accepted general principles of the treatment at present adopted for this condition; nor is it claimed that the striking progress observed in one of the two cases reported was brought about by this particular form of treatment. It is recognized that the natural history of coeliac disease could itself account for the improvement that took place, and that the part played by skilful nursing, a low-fat diet, and a high vitamin intake was no doubt important in determining this improvement. The method is therefore put forward on the grounds of having a rational and scientific basis and possessing distinct advantages over other methods of ensuring a high protein intake in the treatment of this disease. Finally, it is hoped these advantages, together with the freedom from technical difficulties in the preparation of proteolysed beef, will be considered of sufficient merit to promote further and more extensive clinical trials.

Method of Preparation of Proteolysed Beef

The method used for the preparation of the material is a modification of that described for the proteolysis of liver by Davis *et al.* (1943). Six pounds of minced lean beef are placed in a steam-pan together with 15 g. of papain and 30 oz. of water. The mixture is heated to 60° C. and maintained at this temperature for three hours. The material is then raised to 100° C. and vigorously boiled for 10 minutes. The hot digested mixture is strained through cloth, cooled in a refrigerator, strained to remove residual fat, and the volume adjusted to 6 pints with water. The resulting clear solution is stored in a refrigerator, and one pint for each patient issued to the ward daily.

Advantages of Proteolysed Beef

(1) Proteolysed beef yields in concentrated solution first-class protein in the form of easily digested and assimilable peptones, oligopeptides, and amino-acids. (2) The digest is free from indigestible and particulate matter such as fibrous tissue. (3) Being reduced to a small volume (20 oz.), the equivalent of 1 lb. of beef a day can be taken by a young child over an indefinite period, whereas the use of a similar quantity of redigested beef would not be feasible. (4) Proteolysed beef is not unpleasant to the taste, and resembles broth; but what is more important is that it is taken readily and sometimes eagerly by young children. (5) The absence of serious technical difficulties renders the routine preparation of the digest a practical proposition in any hospital possessing a well-equipped dispensary.

Method of Administration of Proteolysed Beef

The digest keeps satisfactorily for 5 days if stored in a refrigerator. This allows of not too frequent preparation as well as of keeping a ready supply in the ward. Being in liquid form and of the consistency of broth, proteolysed beef is most conveniently given to young children as a 5-oz. drink, or be taken with the main meals and in the mid-morning or afternoon tea. It may be given hot or cold; on the whole the former is preferred by the patients. Although to give four cups of soup of doubtful brew sounds a wearisome gastronomic outburst—as it would be to most adults—this does not appear to be the case with young children. Both the patients whose cases are reported took the digest readily from the beginning, and rarely refused feeds, even after nearly 12 months' continuous administration. During exacerbations, when abdominal distension and vomiting were pronounced, the feeds were sometimes refused. It has usually been found, however, that when for any reason the digest was refused other forms of nourishment were likewise rejected. During all except the most severe intercurrent illnesses the feeds were continued. A number of other children in comparable age groups and suffering from different complaints were given the digest for short periods without difficulty.

Feeding with proteolysed beef contrasted most favourably with a 9-week period during which bananas were given to the older patient. The "banana course" was concluded a week before the proteolysed-beef therapy was begun, and was, by comparison, a dismal failure. The patient showed a dislike for bananas from the beginning, however cunningly they were prepared or camouflaged; she had to be watched while she ate them, and even with this precaution managed on occasion to secrete them under the pillow or among the bedclothes. In short, no detectable benefit accrued from the feeding with bananas in this case, while much inconvenience was caused to both patient and nursing staff. In regard to difficulties or disadvantages in the administration of proteolysed beef there is nothing to be said, for none were encountered, even after nearly 12 months.

Report of Two Cases

Case 1.—A girl aged 3½ years was admitted to Southend General Hospital on June 10, 1942. She had been healthy and robust until her second year, when the passage of frequent and offensive frothy motions associated with abdominal distension and progressive loss of weight set in. Deterioration in her condition had been steadily progressive, so that on admission she weighed only 13 lb. 13 oz., whereas at the age of 18 months her weight was 24 lb.

Examination revealed a typical picture of advanced coeliac disease; marasmus extreme; eyes sunken and dehydration marked. The

abdomen was only moderately distended, but, together with a relatively normal face, contrasted sharply with a wasted, shrunken, and under-developed body. The stools, not more than three in 24 hours, were fluid, yellow, and offensive. Dehydration was overcome by rectal glucose-saline, while the standard treatment* was gradually introduced towards the end of the second week. During this period her weight increased by 3 lb., chiefly owing to fluid retention; for a nutritional type of oedema developed in the lower extremities. **Blood count:** Hb 82%; C.I. 0.88; W.B.C. 16,000, with a normal differential count. Progress remained slow and uncertain, a gain in weight one week being offset by a loss the next. Large offensive stools averaged three in 24 hours, while bouts of vomiting, with gross abdominal distension and much flatulence, occurred every few days.

Nov. 11, 1942: Ascites developed for no apparent reason. **Weight 23 lb. 8 oz. Nov. 19:** Developed lobar pneumonia, successfully treated by chemotherapy. Ascites subsided spontaneously during this illness. **Nov. 23:** Weight 17 lb. 4 oz. **Dec. 3:** Otitis media, with purulent discharge from left ear. Hb 67%; C.I. 0.8; W.B.C. 7,850, with normal differential count. **Jan. 1, 1943:** Critically ill for two weeks with dysentery. **Weight 23 lb. 8 oz. B. sonnei** cultured repeatedly from stools until **March 1.** **Weight 20 lb. March 19:** Developed tetany, with carpo-pedal spasm and much pain; relieved by calcium gluconate intravenously, but persisted in latent form for one week. **Blood calcium 6.3 mg. per 100 c.cm.** Radiographs showed gross generalized rarefaction of bone. **Weight 22 lb. 8 oz. April 1:** Bananas added to diet (three daily) for 9 weeks; taken only with difficulty and persuasion. Bowel actions two per 24 hours, but vomiting became more frequent during this period. **May 5:** Neohepatex 4 c.cm. intramuscularly weekly for 10 doses. **June 22:** Bananas discontinued. **Weight 21 lb. 12 oz.**

June 29 (Proteolysed-beef therapy begun): **Weight 21 lb. July 25:** **Weight 20 lb. 4 oz. Sept. 26:** **Weight 21 lb. 3 oz. Oct. 11:** Vitamin K 5 mg., D.O.C.A. 5 mg., riboflavin 1 mg., and nicotinic acid 50 mg., given intramuscularly daily for one month. **Weight 20 lb. 5 oz. Nov. 11:** Parenteral vitamins discontinued. **Weight 21 lb. Jan. 30, 1944:** **Weight 21 lb. Feb. 8:** Massage and bed exercises begun. **Weight 23 lb. March 1:** Able to sit in chair. **March 11:** Fell from chair, sustaining a subperiosteal fracture of right humerus. **March 14:** Developed alveolar abscess, treated by tooth extraction. Bowel actions 1 to 2 per 24 hours. Motions semi-solid and less offensive; vomited once in four weeks. **Weight 27 lb. April 17:** Able to walk with assistance. **Weight 31 lb. 4 oz. May 11:** Fell, sustaining subperiosteal fracture of right tibia. Bowel actions 1 to 2 per 24 hours. No vomiting for 7 weeks. **June 1:** The child, fresh-complexioned, looks healthy, and, apart from a distended abdomen, is normally proportioned, although considerably undersized for her years (5 years 5 months). She is precocious and cheerful, and in spite of deficient education is remarkably intelligent. **Weight 35 lb. Examination of faeces:** Total fat content, 29.7% of dried faeces, 6.6% being in neutral form and 23.1% split fat. **Blood count:** Hb 70%; R.B.C. 4,140,000; C.I. 0.8; W.B.C. 6,850, with normal differential count.

Case 2.—This patient, a boy aged 17 months, was admitted to Southend General Hospital on July 6, 1943. He had been a healthy infant until 6 weeks previously, when anorexia, with loss of weight, frequent bowel actions, and recurrent abdominal distension, made an appearance. Vomiting was not a feature.

On examination he was considerably wasted, especially about the buttocks and lower limbs; face pale and bloated; pot-bellied, with umbilicus everted. **Weight 16 lb. 8 oz. Blood count:** Hb 76%; C.I. 0.8; W.B.C. 7,500, with normal differential count. **Blood calcium 9.8 mg. per 100 c.cm.** Examination of dried faeces showed total fat content of 46.7%, 3.2% being in neutral form and 43.5% split fat. The standard treatment* was at once started, and 1 pint of beef digest included in the diet daily.

July 20: Bowel actions 3 per 24 hours; motions yellow, fluid, and offensive. Bouts of abdominal distension and vomiting occasional. **Aug. 8:** Bowel actions 2 per 24 hours. **Weight 17 lb. 8 oz. Sept. 20:** **Weight 16 lb. 8 oz. Oct. 20:** D.O.C.A. 5 mg., riboflavin 1 mg., and nicotinic acid 50 mg. given daily for one month intramuscularly. **Nov. 11:** Developed acute mastoiditis; treated by operation. Parenteral vitamins discontinued. **Dec. 20:** **Weight 17 lb. 4 oz. Jan. 1, 1944:** **Weight 18 lb. Feb. 8:** Massage and exercises begun; able to stand in cot. **Weight 18 lb. 4 oz. June 1:** Child shows marked improvement. He is lively, happy, and has a good colour. Although thin and undersized, he is by no means wasted. The abdomen is still prominent, but bowel actions have averaged 1 a day for over a month, while the motions are formed. Vomiting has ceased completely. **Weight 22 lb. 4 oz. Examination of dried faeces:** Total fat 31.3%, 5.8% being in neutral form and 25.5% split fat. **Blood count:** Hb 71%; R.B.C. 3,730,000; C.I. 0.9; W.B.C. 12,550, with normal differential count.

* This consisted of a graded fat-free diet with the addition of the following, which were given daily: vitamin D, 6,000 units; nicotinic acid amide, 100 mg.; ascorbic acid, 100 mg.; vitamin B₁, 6 mg.; iron sulphate, gr. 6; calcium lactate, gr. 30.

Summary

A method for ensuring a high protein nitrogen intake in the treatment of coeliac disease and allied conditions by the oral administration of proteolysed beef is described.

Details of the method of preparation of the digest, which can be satisfactorily carried out in any well-equipped hospital dispensary, are given.

Two cases of coeliac disease treated daily with proteolysed beef for 11 months and 10 months, respectively, are reported.

It is hoped that the new method, which is based on the principle of the need for a high protein diet in coeliac disease, will stimulate further clinical trials.

We wish to thank Dr. R. Sleight Johnson, under whose care the patients were admitted to hospital, for permission to publish the case notes, and for his helpful criticism of this paper.

A FRACTURE-DISLOCATION OF THE ANKLE OCCURRING IN FLYING ACCIDENTS

BY

THEODORE JAMES, M.B., Ch.B.

Squad. Ldr., R.A.F.V.R.

Fracture-dislocations of the talus, which before this war were comparatively rare injuries, have become more common as a result of accidents to Service aircraft. It is the intention to describe a typical fracture-dislocation of the ankle, occurring in such accidents, in which the talus bears the brunt of the injury, the manner in which it is produced, and the different kinds of treatment employed.

Description.—The fracture line is irregular and extends obliquely through the neck of the talus; the fragments are widely separated; the head of the talus remains *in situ*, but the body is expelled from the ankle-joint and is rotated around its longitudinal axis through 90° (Fig. 1). The injury is not com-

of the talus, is driven through it; the ankle-joint is deranged and the body of the talus is dislocated posteriorly and rotated about its longitudinal axis.

Diagnosis.—This can be made with certainty only by radiographic examination; but with a knowledge of the history of the injury the provisional diagnosis of a fracture-dislocation of the talus is reasonable.

Treatment

Treatment is to be looked upon as urgent. The talus derives its nutrient vessels by way of the anterior ligament of the ankle-joint for the head and neck and by way of the posterior and lateral ligaments for the body. In this fracture-dislocation the blood supply to the body is cut off and avascular necrosis follows. This has a most important bearing upon treatment.

Reduction.—Closed reduction of the dislocated body, if at all feasible, is extremely difficult. Reduction, therefore, if attempted, should advisedly be open. The foot is then put up in plaster-of-Paris in extreme equinus for at least four weeks, when the sutures are removed, after which the plaster is continued for a further 16 weeks or more with the foot at a little less than a right angle. Care must be taken to ensure that separation of the fragments does not take place while this is being done. Although regeneration of the body after avascular necrosis might follow accurate reduction and prolonged immobilization, degeneration of its articular cartilage in the ankle-joint and in the subtalar joint will occur, to produce a painful and crippling arthritis.

Partial Talcotomy.—This is removal of the displaced body only (Fig. 2). To remove only the body of the talus is not advised. The head remains *in situ*; but the foot as a whole moves proximally, and the head of the talus comes to lie anteriorly to the lower end of the tibia. Backward displacement of the foot is prevented; there is no heel to speak of, and any dorsiflexion that the false joint permits is extremely limited. There is unnecessary painful friction between the anterior margin of the lower articular surface of the tibia and the fractured surface of the head of the talus. Nevertheless, the patient is able to walk several miles, and for a while even to dance after a fashion, with only a modicum of pain and disability. Arthritic

FIG. 1.—Showing the typical fracture-dislocation.

Whereas in posterior dislocations of the talus fracture of a malleolus is held to be an inevitable accompaniment, in this fracture-dislocation the same contention is not valid.

Manner of Production.—It is necessary here to mention a principle of airmanship: when a pilot in a single-engine aircraft is forced to make a crash-landing, before the moment of impact with the ground he puts on either the right or the left rudder. The purpose of this act is to minimize the danger from the engine, which will be dislodged backwards relatively when it strikes the ground. The turn so induced by the rudder increases the chances of the dislodged engine passing to one or other side of the pilot; but it also happens that the engine comes against the rudder-bar, which is pushed forward. The blow is severe enough to dorsiflex the foot beyond its limit and also to force it proximally so violently that the anterior margin of the lower articular surface of the tibia, which impinges against the neck

FIG. 2.—Showing the talus removed.

pains develop and worsen with time. Shortening of the limb by about three-quarters of an inch, and stiffness, produce a marked limp. When the operation wound has healed, a surgical boot with a leg-iron must be worn to allow the deep tissues to consolidate. After 16 weeks the leg-iron is dispensed with, and surgical footwear which allows for the dropped malleoli and almost absent heel is fitted.

Talcotomy.—If talcotomy is the treatment of choice, a comparatively satisfactory result may be obtained if it is performed with the care and attention to detail which are exercised by Laming Evans. The depreciation of this operation is in large measure due to inadequate surgical technique, which can render the results of a badly performed talcotomy irreparable. Again, surgical footwear is necessary to allow for the prominent heel; but much of the limp can be overcome by making the sole and heel about 1½ in. thick, and in conformity with the design of

Mr. C. Denley Clark's "rocker," as he described it in the *British Medical Journal* (1943, 2, 364).

Fusion of Tibia and Os Calcaneus.—Wing Cmdr. W. D. Coltart, in a short paper which he read at the 1943 annual meeting of the British Orthopaedic Association, mentioned a second-stage operation—fusion of the tibia and the os calcaneus. This is still on trial.

Arthrodesis.—Where expert operative technique is available this should be the treatment of choice. It is needless to prolong treatment by employing reduction first. Arthrodesis should be the only operation. It is the surest way to stabilize the foot and to prevent an ever-worsening disability. It also obviates noticeable shortening of the limb, and to a great degree the limp, which can become almost imperceptible if the patient shortens his walking pace.

A SURVEY OF THE HAEMOGLOBIN LEVELS OF THE POOR CLASSES IN ABERDEEN

BY

H. W. FULLERTON, M.D., M.R.C.P.

M. ISOBEL MAIR, M.B., Ch.B.

AND

PATRICIA UNSWORTH, M.R.C.S., L.R.C.P., D.P.H.

(From the Department of Medicine, University of Aberdeen)

It was shown by Davidson, Fullerton, and Campbell (1935) that iron-deficiency anaemia was common among the poor classes in Aberdeen and that the anaemia was to a large extent caused by the ingestion of diets low in iron. Several somewhat similar surveys have been made recently with the object of determining what effect war conditions have had on the haemoglobin levels of different sections of the population (Davidson *et al.*, 1942, 1943; Mackay *et al.*, 1942). It was felt that it would be particularly useful to carry out such a survey in Aberdeen, since the results obtained in this city could be compared more fairly with the 1935 survey than figures obtained in other areas. Accordingly, the work here briefly reported was started early in 1943 and was completed early in 1944. Throughout the investigation Haldane haemoglobinometers which had been tested by the National Physical Laboratory were used, and the appropriate correction factors have been applied to all the results. The Haldane haemoglobinometers used in the 1935 survey were carefully standardized with the oxygen capacity method.

It soon became apparent that the investigation could not have exactly the same scope as that reported in 1935. Apparently the results of the pre-war survey have been admirably appreciated by the medical officers in charge of mother and child welfare and other clinics, so that it is now impossible at many centres to find a representative cross-section of the population which has not at some time had iron therapy. For this reason we have excluded infants from the present survey. A similar difficulty was encountered at antenatal clinics, where iron is freely dispensed to all women who are judged clinically to be anaemic. Therefore haemoglobin estimations have been restricted to women attending such clinics for the first time. Within the limitations imposed by these circumstances the results of the 1943 survey can be fairly compared with those of 1935, as the subjects belonged to the same social groups, with one exception which will be dealt with separately.

Results

To facilitate comparison most of the results are presented graphically in the accompanying Chart, and only a short description of the results in each age group is necessary.

Children of Nursery-school and School Age (2 to 11 years).—The average haemoglobin levels both in 1935 and in 1943 show in general a gradual rise with increasing age. The results in 1943 are distinctly higher than those of 1935 until the age of 7 years onwards, when the curves converge. Table I shows the percentage of subjects in each decimal range of haemoglobin level. The incidence of anaemia in pre-school children was much less in 1943 than in 1935, but it is rather surprising to

find, among the school-children of the 1943 survey, several instances of mild anaemia, in contrast with its absence in 1935. It may be pointed out that the figures for 1935 are more significant than the small numbers of subjects indicate, since haemoglobin estimations were made at that time in an additional

Chart showing average Hb levels at different ages. The figures represent the numbers of subjects examined.

group of 100 school-children. In only 2 of them was the haemoglobin level less than 80%, and in both it was greater than 70%. This group is not included in the graph or table, as the ages were not noted.

TABLE I.—Incidence of Anaemia in Children

Age (Years)	No.	Haemoglobin Range (%)										Av. Hb
		10-14	15-19	20-24	25-29	30-34	35-39	40-44	45-49	50-54	55-59	
2-3	19	16	5	—	—	—	—	—	—	—	—	73.0
4-5	16	35	—	—	—	—	—	—	—	—	—	79.4
6-7	9	31	—	—	—	—	—	—	—	—	—	83.1
8-9	14	50	—	—	—	—	—	—	—	—	—	86.9
10-11	42	—	—	—	—	—	—	—	—	—	—	89.4
12-13	52	—	—	—	—	—	—	—	—	—	—	90.8
14-15	75	—	—	—	—	—	—	—	—	—	—	90.8
16-17	75	—	—	—	—	—	—	—	—	—	—	90.8
18-19	27	—	—	—	—	—	—	—	—	—	—	91.4
20-24	45	—	—	—	—	—	—	—	—	—	—	92.0
25-29	54	—	—	—	—	—	—	—	—	—	—	93.9

Adolescent Girls (engaged in Industrial Work and attending a Social Club).—The Chart shows a curious discrepancy between the results of the two surveys. In 1935 the average haemoglobin level for the group aged 15 to 19 years was 94.4%, while in 1943 it was 81.3%. The numbers of subjects in these two groups are 133 and 157 respectively, so that the difference is a significant one. The incidence of mild anaemia (haemoglobin less than 80%) was considerably higher in 1943 than in 1935.

Adolescent and Adult Males (engaged in Industrial Work and attending a Social Club).—132 subjects in this group were examined in the 1943 survey; to avoid confusion they are omitted from the Chart. The results are similar to those found in 1935. The average haemoglobin level of the 15-19 years group was 94.1%, while in 1935 it was 98.8%. Significant degrees of anaemia were not found.

Pregnant Women (attending Antenatal Clinics).—The Chart shows that the average haemoglobin level for each age group was distinctly higher in 1943 than in 1935. Moreover, the decrease in the average levels with increase in age which was found in 1935 was absent in the present survey. The percentages of subjects in each decimal range of haemoglobin level are

TABLE II.—Incidence of Anaemia in Pregnant Women

	No	Haemoglobin Range (%)								Average Hb
		30-39	40-49	50-59	60-69	70-79	80-89	90-99	100-109	
1935	819	0.5	1	4	12	32	33	12	0.5	78.1
1943	301	0	0	0.3	3.6	31.5	50.5	13.3	0.6	82.6

shown in Table II. In 1935 17.5% of the women examined had moderate anaemia (haemoglobin less than 70%) as compared with only 3.9% in 1943. This discrepancy cannot be attributed to any difference in the duration of pregnancy

between the two groups, since the percentages of subjects examined in each month of pregnancy were approximately the same in 1943 as in 1935. The degree of parity of the subjects in the 1943 survey was slightly less than in 1935, but it has been clearly shown by one of us that this cannot be correlated with the incidence of anaemia in women of the same age groups (Fullerton, 1936).

Nurses.—205 members of the nursing staff of Aberdeen Royal Infirmary were examined. Since a similar group was not included in the 1935 survey the results are presented separately in Table III.

TABLE III.—Haemoglobin Levels of Nurses

Age	No.	Average Hb
18-19	48	86.0
20-24	122	88.8
25-29	15	88.8
30+	20	91.7

No haemoglobin level less than 70% was found, and only 2 were less than 80%.

Discussion

It is not proposed to discuss in detail the possible implications of the results. The striking finding is the improvement which has occurred in the haemoglobin levels of young children and of pregnant women, and it may be deduced that a similar improvement would be found in non-pregnant women. No attempt has been made in the present survey to estimate the iron content of the diets taken by the different groups, but it seems possible that the greater iron content of the national bread may explain, at least in part, the higher haemoglobin levels found in 1943. We are unable to offer satisfactory explanation of the increased incidence of anaemia in girls between the ages of 15 and 19. It is possible that a detailed knowledge of the conditions of their work and its effect on appetite and menstrual loss might throw some light on the problem.

Summary

Haemoglobin estimations in 1,177 subjects belonging to the poor classes in Aberdeen have been compared with the results of a similar survey carried out in 1935. The incidence of anaemia in young children and in pregnant women was less in 1943 than in 1935, but it was greater in girls between the ages of 15 and 19. No significant difference was found in adolescent and adult males.

We are indebted to the Public Health Department of the City of Aberdeen and to St. Katharine's (Y.W.C.A.) Club for facilities that have made this survey possible, and to the Public Health Committee of the Aberdeen Town Council for financial assistance. We wish to thank Prof. R. S. Aitken for his interest and help.

Medical Memoranda

"Silent" Mastoiditis or Mastoiditis due to *Str. mucosus capsulatus* of Schottmüller

The following case stresses the importance of bearing in mind the incidence of this type of mastoiditis (called also atypical, asymptomatic, or primary, etc.), and of operating on the patient before he has developed intracranial complications, with a consequent poor prognosis.

CASE HISTORY

On Dec. 5, 1943, a woman aged 38, rather stout, but well nourished and in good health, felt that her left ear was "blocked." At the same time she had mild intermittent pain in the left ear, especially at night. There were no other constitutional symptoms. After a week she went to see her doctor, mainly for the deafness and sense of "blockage" of the ear, which he syringed. After three hours she became sick and giddy, and this lasted for half an hour. The pain got worse and spread towards the back of the head. She had had no cold or sore throat preceding this, and no past history of ear trouble. There were still no constitutional symptoms.

On Jan. 28, 1944, she was seen at the out-patient department, where the only abnormal clinical finding was that the left tympanic membrane was pink. Radiographs of mastoids showed them to be

of a very cellular type with definite blurring of the left cells, but no cavity or sequestrum could be observed. On Jan. 31 she was seen again, and was ordered inhalations and guttae acid. boric. c spirit. On Feb. 7 there was hardly any pain, and she thought she was relieved. On examination there was sagging of the external meatal wall and the drumhead could not be seen. The patient was admitted for observation against her wish, as she thought she was well enough to go home. She was under observation for a week, during which time there was no rise of temperature, pain, discharge, or constitutional disturbance.

On the night of Feb. 13 she developed severe pain again, and had some oedema and tenderness over the mastoid antrum. On the 14th the swelling was more pronounced. The temperature was never above 99° F. Blood count: total W.B.C., 8,400—polys 70%, lymphs 28%, hyalines 2%. The mastoid was opened on Feb. 15, and was found to be of a cellular type, full of pus and granulation tissue, with necrotic bone, and at the same time there was an extradural abscess. Culture of the pus revealed the organism to be pneumococcus Type III. She made an uneventful recovery and was discharged on March 23. Since then she has been in perfect health and has had no recurrent ear trouble.

I wish to express my thanks to Mr. T. P. Gill, honorary surgeon to the hospital, for encouragement to report this case.

Accidental Haemorrhage in Two Successive Pregnancies within 16 Months

The case of a patient suffering from accidental haemorrhage in two successive pregnancies seems rare enough to merit publication.

CASE HISTORY

Mrs. X, aged 33, was admitted as an emergency case on Jan. 17, 1943. She had had two previous pregnancies and two miscarriages. The first pregnancy, in 1928, was normal, but labour was premature at 8 months, the child weighing 3 lb. This child is alive and well. The second pregnancy, in 1931, went to full term, but the child died of fits at 3 months. Then followed two early miscarriages. The patient did not become pregnant again for 12 years, and was then admitted here.

She was collapsed and pulseless on admission, with jaundiced pallor, blanched mucous membranes, and air hunger. There was gross oedema of hands, face, and legs; the urine was solid with albumin; and the blood pressure was 92/50. The uterus was the size of a 26-weeks pregnancy but should have been 34 weeks by dates (date of expected delivery, early March). It was typically tender and woody, and with no F.H. and no foetal parts. There was a very slight vaginal loss. A blood transfusion was started, the membranes ruptured, and a pad and binder applied. An injection of morphine gr. 1/4 had been given on admission. Spontaneous breech delivery occurred 6 hours later. The placenta was completely infarcted and ploughed up by a large retroplacental clot. There was no post-partum haemorrhage. The child was stillborn and weighed 2 lb. 14 oz. The puerperium was very satisfactory; the anaemia improved with large doses of iron, the blood pressure remained steady at 128/88, and the urine was albumin-free. Birth control advice was given.

In Jan., 1944, the patient, having failed to carry out the birth control advice given, was 3½ months pregnant. Her general condition was good; blood pressure and urine normal. She was advised to attend the clinic regularly. The date of expected delivery was June 4. She was admitted to hospital on May 9 with anaemia and mild toxæmia. The blood pressure was 140/90; there was slight oedema of feet, but no albuminuria. The treatment was absolute rest and large doses of iron.

On May 12 she suddenly collapsed in the antenatal ward with severe abdominal pain. She was cold, clammy, and restless, and the pulse was very poor. There was no vaginal loss. The blood pressure fell to 86/64. The uterus was tender and obviously enlarging with concealed haemorrhage. A continuous drip transfusion was started, morphine was given, and a vaginal examination made. The membranes were not bulging and there was absolutely no vaginal loss. However, it was deemed wiser to try to stimulate the uterus, so the membranes were ruptured and a pad and binder applied. The case seemed hopeless during the next few hours, as there were no pains and the uterus was enlarging rapidly; but, fortunately, contractions did start, and 9 hours after the membranes were ruptured a spontaneous breech delivery occurred. The placenta followed immediately, grossly infarcted with a large retroplacental clot, roughly 6 by 6 by 4 in., and about half a pint of old fluid blood. There was also a clot the size of a hen's egg between the foetal surface of the placenta and the cotyledons. The child was stillborn and weighed 3 lb.

Progress was slow but steady in the puerperium. The anaemia rapidly improved, the blood pressure remained at 118/76, the oedema subsided, and the urine remained clear. The patient was discharged, feeling better than she had done for some time. She was advised very strongly to avoid further pregnancies.

Two accidental haemorrhages within 16 months must be a rare occurrence. The toxæmia was never pre-eclamptic in severity, the onset was sudden in each pregnancy, and residual symptoms, except for slight secondary anaemia, were non-existent.

Reviews

VITAL STATISTICS IN THE TROPICS

Vital Statistics and Public Health Work in the Tropics By P. Granville Ed., Foreword by Prof. Major Greenwood D.S. FRCP FR S (Pp 188 12s 6d) London Baillière Tindall and Cox 1944

Only by losing some of our tropical colonies for the time being have we been really awakened to their value to ourselves and to the world at large, and to our own shortcomings in past dealings with them. In his foreword to this book Prof. Greenwood reminds us that 'there are colonial territories administered by us the vital bookkeeping of which is far cruder than that of the home country three hundred years ago.' Major Edge is convinced from his own experiences that the urgently needed improvements in this sphere, essential as he shows them to be for efficient administration, will not be achieved by slavish application of European procedures and practices to tropical areas where social organization and conditions of life are so vastly different. He approaches the special problems which these colonies present to vital statisticians, public health workers, and administrators, whose hearts are in the work, in a realistic and sympathetic way, and in successive chapters deals with census enumerations, birth and death registration, morbidity records, and nomenclatures of disease. In devising systems for building up a framework of even the elementary facts he stresses the need to take careful account of the peculiarities of each people as regards their attitudes, superstitions, taboos, and social customs, and provides many illustrations of the misleading conclusions which may otherwise result. An unfortunate error occurs on page 96, where it is stated that 'the English registration system makes no provision for the registration of the age of mothers at the time of the birth of successive children nor for recording the order of such births.' The Population (Statistics) Act of 1938 remedied this defect, and such information has now been obtained at birth registration for more than six years. The book, which is well furnished with references to English publications, is likely to give both help and encouragement to those engaged in public health activities in tropical countries.

A SUMMARY OF MODERN PSYCHIATRY

Fundamentals of Psychiatry By Edward A. Strecker M.D. Sc.D. F.A.C.P. (Pp 192 12s 6d) London Medical Publications Ltd.

As the author rightly says, the general physician must nowadays know about psychology, and if that is true of America it is equally true here. This little volume gives a concise, clear, and (in spite of what we call Americanisms) readable summary of modern psychiatry which the consultant and specialist in all branches may read with great advantage to himself and his patients. It is very suitable also for the general practitioner, though his need is less urgent. The author has a balanced view about his subject and on the whole steers clear of jargon, but lapses once when he talks about oral and anal types. The only criticism which might be advanced is that there is not enough about the psychoneuroses—only 12 pages compared with 21 on schizophrenia alone. The latter is a very interesting and important disease, but after all it is nothing like so common as the psychoneuroses, which throng the general wards and out-patient departments of all hospitals. In his approach to the psychoneuroses Dr. Strecker is obviously the institution psychiatrist and lays too much stress on the grosser physical manifestations of conversion hysteria and the acute angor attacks. He still talks about neurasthenia while admitting that the fatigue is due to emotional conflict, and he perhaps stresses the reactive type of anxiety too much as compared with the true psychoneurotic anxiety arising from unconscious conflict.

The chapter on war psychiatry is based on the hearsay evidence of visitors from Britain on the effect of bombing on civilians, but there is nothing about the effect of evacuation on children. So far as Service psychiatry is concerned the author's remarks are based on his own experience at Chateau Thierry in the last war. We are, however, probably too near the process to be able to estimate the effect of the present war on the psychic make up of this generation, and we cannot yet be

sure that the observations of the last war are applicable to present day problems.

If all doctors who are not psychiatrists were to read and digest this book—and it would not take them long—their practice of medicine would be vastly improved.

WHOOPIING-COUGH

Whooping Cough By Joseph H. Lapin M.D. (Pp 238 illustrated 25s) Springfield and Baltimore Charles C. Thomas London Baillière Tindall and Cox 1943

As this disease is now the most dangerous of all the specific fevers a monograph on whooping cough is very timely, and Dr. Joseph H. Lapin has skilfully analysed the literature to aid his own extensive experience in this disorder. He describes the epidemiological and bacteriological aspects before proceeding to the problems of immunity and the serological reactions. Chapters on clinical manifestations and on diagnosis give a clear picture of everyday problems, and next come sections on prevention and treatment in which, naturally, prominence is given to the use of vaccines. Non-specific treatment—on which there is so much literature that suspicions of its complete ineffectiveness are raised—is carefully considered. The treatment of complications and a section with suggestions for the administrative control of the disease complete the volume, which has a good index.

Prof. P. M. Stimson in a foreword describes this book as "a valuable contribution to the literature of the disease," and this can be heartily endorsed. At a time when modern chemotherapy and biological products have done so much to rob other specific fevers of their perils it is important that the unsolved problem of whooping-cough should receive serious attention. Dr. Lapin has performed an important service with his monograph, which can be warmly commended.

ASEPSIS IN EXCELSIS

Micurgical and Germ-free Techniques. Their Application to Experimental Biology and Medicine. A Symposium Edited by James A. Reyniers (Pp 274 illustrated \$5.00 or 2s 6d) Springfield and Baltimore Charles C. Thomas London Baillière Tindall and Cox 1943

This volume edited by J. A. Reyniers embodies papers read at a colloquium at the University of Notre Dame, Indiana, in 1939. The title *Micurgical and Germ-free Methods* on the cover is varied on the title-page by substituting the word "techniques" for "methods." Neither version will convey to most readers what the book is about, and it should be explained that "micurgy" is apparently more or less synonymous with micro-manipulation, while "germ-free methods" refers to the maintenance of animals and plants under bacterially sterile conditions. There are three chapters on the first of these subjects and five on the second, while three final chapters deal with another subject altogether, though admittedly related to the second—the control of cross infection by air-conditioning, mechanical barriers, and ultra violet light.

In this oddly heterogeneous collection of papers there is much of interest to the microbiologist, and something for those concerned with several other branches of science besides. Micro-manipulation makes it possible to inject materials into individual cells and watch the effects; some indications are given of the uses to which this remarkable method can be put. The most sensational achievement described in the book is the rearing of a germ-free monkey, whose portrait appears in two places, and the projected extension of such studies to goats and calves will call for elaborate machinery on an even larger scale. Animals so reared are of course delivered by Caesarean section, and are kept in "cages" having rather the appearance of horizontal autoclaves with windows, and apertures to which long-sleeved rubber gloves are fitted for interior manipulation. Sterile air is supplied to them, and food is steam-sterilized in a "foodclave," the space between double doors communicating with the interior. The monkey which had been kept germ-free for four months at the time of writing had a more adventurous sister who contaminated herself with staphylococci and other organisms by puncturing a rubber glove and eventually "fell into" a glove and was suffocated. Other chapters in this section deal with the germ-free cultivation of protozoa, nematodes, and insects, with the use of the mammalian foetus as an experimental animal, and with the germ-free cultivation of plants.

The whole book very properly deals with methods rather than results, but much is said about what they may be expected to achieve. While we must admire the enterprise of those who have perfected these exceedingly difficult techniques, it remains to be seen whether they will add to knowledge to an extent commensurate with the trouble and expense involved.

Notes on Books

Medical Photography: Radiographic and Clinical, by T. A. LONGMORE, is published by the Focal Press at 25s. This book has a twofold purpose. The first half is devoted to the photographic aspects of radiography, and the second to clinical photography in all its aspects. There is a wealth of information in both parts. In the radiographic section, clinical radiographic technique is by design omitted, and the radiographic student must turn elsewhere for instruction in the art of positioning the patient, but the photographic aspects are dealt with in a manner that merits commendation. The descriptions are simple and concise and the illustrations

well chosen and informative. The section begins with an account of the production of the photographic image, and goes on to describe x-ray apparatus, accessories, and dark-room technique. It finishes with an excellent summary of faults in radiographs. The second section, on clinical photography, covers the field from the physics of optics to the completed print, and a final section deals with special techniques such as mass miniature radiography, tomography, colour reproduction, microphotography, and cinephotography. The book ends with an appendix of formulae and a glossary of terms. It is warmly to be recommended to all engaged in radiographic or clinical photographic work.

The fifth edition of a *Handbook of Ophthalmology*, by Mr. HUMPHREY NEAME and Mr. F. A. WILLIAMSON-NOBLE (J. and A. Churchill; 18s.), follows closely on the previous edition published in 1942, but it is not a mere reprint. The authors have taken the opportunity to incorporate the modifications in treatment produced by the sulphonamides, and have considerably revised the sections dealing with operative procedures. The newer work on vitamin therapy is also noted. The revision greatly enhances the value of this excellent handbook.

Preparations and Appliances

AN AURAL SYRINGE

Mr. LIONEL COLLEDGE, F.R.C.S., writes:

Dr. Lester Mead Hubby described in Nelson's *Loose Leaf Surgery of the Ear* an apparatus devised by Dr. E. P. Fowler to take the place of syringing by hand.

Mr. Percy Phelps (of the firm of Messrs. Mayer and Phelps) has designed a simpler apparatus in which the force of gravity is used to produce a stream of warm water at a pressure of approximately 11 lb. to the square inch, which corresponds to

top of the tank a pipe (D), controlled by a valve (E), leads to three points (F), each point being controlled by a separate valve. To each point a length of flexible rubber tubing (G) is attached ending with a nozzle (H) suitable for syringing the ear and easily controlled by one hand. Near each irrigating point a small receptacle (J) is fitted, connected to the waste pipe (K) to carry away waste water. A valve (L) is fitted to the tank in order to draw off water rapidly in case of need.

This apparatus has now been in use at the hospital in Golde Square for more than five years, and has proved safe, rapid

FIG. 1

FIG. 2

the power of a Wood's aural syringe when used efficiently by hand.

The apparatus of Mr. Phelps consists of a tank (A) of 10 gallons capacity fitted at a convenient height on the wall, and connected to this tank is the feed water tank (M). This feed tank is placed at the height of 25 ft. above the main tank (A), at which height the pressure of water is maintained at approximately 11 lb. per square inch. Fitted to the main tank is an electric immersion heater (B), controlled by a thermostat which maintains the water in the tank at a constant temperature of 100° F., indicated by a thermometer (C). From the

clean, and efficient. It reduces greatly the labour of syringing a long series of ears and thereby eliminates the fatigue which introduces an element of danger when such syringing is done by hand. One nurse can easily syringe fifty ears during an afternoon clinic; and, since the introduction of the apparatus, bleeding from minor injuries to the meatus and granulations has no longer occurred, nor has there been any case of perforation of the tympanic membrane, an accident which before then occasionally, though rarely, occurred. The total cost of making and installing the apparatus was less than £100, which has been more than repaid in these days of shortage of staff.

MERSALYL B.D.H.

In addition to its general use in early nephritis, nephroses, hepatic ascites and cardiac oedema, Mersalyl B.D.H. may be used also in the treatment of polyserositis, eclampsia (in the absence of acute pyelonephritis), Ménière's disease, obesity, thrombophlebitis and the oedema of toxic goitre.

It is probable that the diuretic potency of Mersalyl is inseparable from some degree of toxicity. Reactions are comparatively rare, however, and the beneficial effects of the use of Mersalyl are such that the few reactions reported are "*not an indication to withhold the drug but rather to use care in administering it.*" (Lancet, May 8th, 1943, p. 576).

For intravenous or intramuscular injection —

Ampoules of Mersalyl B.D.H. (Injection of Mersalyl B.P.)

For oral administration —

Tablets of Mersalyl B.D.H. (Mersalyl B.P., 0.08 grm., with theophylline 0.04 grm.)

For rectal administration —

Suppositories of Mersalyl B.D.H. (Mersalyl B.P., 0.4 grm. with theophylline 0.2 grm.)

Details of dosage and other relevant information will be gladly supplied on request.

MENAPHTHONE-BOOTS

ANTI-HAEMORRHAGIC

The value of the synthetic vitamin K analogues in the prevention of haemorrhage in the newborn is now established.

"It is probably advisable to give menaphthone either to every mother or to every new born child as a prophylactic against haemorrhagic disease" (*Lancet* 1944, I, 508).

Tablets of Acetomenaphthone Boots are available for prophylactic administration to the mother before delivery.

YELLOW FEVER EPIDEMIOLOGY AND CONTROL

For many years the mosquito *Aedes aegypti* was considered to be the only vector of yellow fever, and all attention was focused on it in attempts to eradicate the disease. Such indeed was the case in Panama and Cuba, and with the elimination of the mosquito the disease disappeared. Anti-*aegypti* measures have also kept the disease under control in urban communities in Africa and South America. The methods of *A. aegypti* control used in South America, which have recently been described by Soper *et al.*¹ have, however, failed to prevent the spread of yellow fever in areas in which it is endemic in Africa, and in the regions in which jungle yellow fever is prevalent in South America, where no *A. aegypti* have been found. In Brazil, in 1938, Shannon and his co-workers² reported finding the virus in the mosquitoes *Aedes leucocelaneus*, *Haemagogus capricornis*, and a species of sabethine caught in those forest regions where the disease was endemic. The disease chiefly affected the men working in the forest, the wives and children at home being relatively unaffected. The problem that was most difficult to understand was how and where the virus managed to exist during the dry season. It has been suggested that the infection was maintained in certain vertebrate hosts such as the monkey, many of which were said to have died in certain regions just before the occurrence of human cases, but, though 20% of the sera of monkeys in the endemic areas in both South America and Africa have been shown to contain yellow fever immune bodies, the exact part monkeys play in the maintenance of the disease has not been understood. Bugher and his colleagues,^{3,4,5} who have been carrying out extensive immunity studies of the fauna in Colombia for a number of years, have recently been able to throw some light on the epidemiology of the jungle yellow fever in that country. They have found that *Haemagogus capricornis* caught in the tree tops in the dry season are infected, and as the mosquito remains infected for life the virus can be carried over into the next breeding season at the beginning of the rains. Though virus was never isolated from them, common opossums, *Didelphis marsupialis*, trapped in the same region where infected *Haemagogus* were found developed immune bodies in their sera during the first 30 days of their captivity. Immune bodies were also found in some of the cebus monkeys caught in these regions. It small doses of virus are inoculated subcutaneously in the animals, there is an incubation period of 3 to 8 days. The virus then appears

in the circulating blood for 3 to 7 days. During this time the animals appear quite well, and are, of course, permanently immune after infection. Bugher *et al.* conclude from these findings that jungle yellow fever in Eastern Colombia is primarily a disease of jungle animals, being transmitted from animal to animal by certain mosquitoes which are strictly forest inhabitants. Mahaffy and his colleagues⁶ have also been able to clarify the position somewhat in Uganda by catching infected *Aedes simpsoni* in the areas where they have recently isolated the virus from man for the first time.

The only means known at present of combating the jungle disease is by mass prophylactic vaccination, which is also combined with *aegypti* control in urban communities in epidemic and endemic areas. The vaccine used has gradually improved since the discovery of the virus in 1927. Though the French have continued to use neurotropic mouse-brain virus, all other interested countries have adopted the attenuated 17D strain of virus developed in the Rockefeller laboratories and grown in the chick embryo. The vaccine consists of infected embryo dried from the frozen state *in vacuo* in ampoules. Because of its instability unless kept at low temperatures, it is distributed to special centres only. Since human serum was eliminated from the vaccine several years ago no cases of jaundice have been produced by serum-free vaccine. This vaccine has for the most part produced little or no reaction after inoculation, and a satisfactory vaccine produces demonstrable neutralizing antibodies in about 95% of inoculees from 2 weeks to a month after inoculation. Though antibodies usually cannot be demonstrated for at least 10 to 14 days after inoculation, a small amount of experimental evidence and field observations indicate that anyone bitten by an infected mosquito 7 days or more after a satisfactory vaccination will be protected or have a modified attack. Certain batches of vaccine which have been shown to have apparently adequate amounts of virus as measured by titration in mice have failed to produce satisfactory immunity in man. Alterations in antigenicity appeared to have taken place in some instances during a comparatively small number of passages in chick embryo. To obviate this danger most centres now make their vaccine by inoculating embryos with "seed lots" of virus from a large batch of vaccine known to produce satisfactory immunity. Even so, it is desirable that each batch be tested for its ability to produce immune bodies in a small group before being issued. It has been found that if each individual receives 500 mld for mice, about 98% of those immune one month after inoculation still have immune bodies 4 years later. In fact Bugher has found that among over 600,000 persons vaccinated in Colombia there had been only one recognized case of yellow fever—this in a boy inoculated only 5 days before he became ill and when he was presumably already infected, 198 proved and 45 probable cases had been recognized among the non-vaccinated since vaccination began. Many of these cases occurred in known epidemic areas where over 90% of the population were vaccinated. Similar results have been achieved in many areas in Brazil, and the scarcity of cases in the vast numbers of

'Stypven' RUSSELL VIPER VENOM

the most effective local hæmostatic yet discovered

A dilute solution of Russell Viper Venom is the most effective local hæmostatic which has so far been discovered. It may be used in all types of hæmorrhage where the solution can be applied directly to the bleeding

point. 'Stypven' is invaluable in emergency when hæmorrhage cannot be controlled by every-day methods. It is also being increasingly used in place of brain extract for the measurement of prothrombin time.

Dried venom and solvent to make 1 c.c., 1:10,000 solution, 1/6 (Purchase Tax 2½d.)

Dried venom and solvent to make 5 c.c., 1:10,000 solution, 3/0 (Purchase Tax 4½d.)

vaccinated personnel exposed since 1939 in endemic and epidemic regions of Africa is ample proof of the efficacy of the vaccine when it is properly handled. There are still numerous areas where *A. aegypti* may be found in countries linked to yellow fever endemic areas by air service. Though anti-*aegypti* control is exercised in the region of the aerodromes in most instances, it is necessary that individuals passing through an endemic yellow fever area and entering Egypt or India shall have been inoculated against yellow fever at least 10 days before entering that country.

SUBDURAL HAEMATOMA IN INFANCY

Chronic subdural haematomas have become commonplace in the past five years, and in the adult the picture of increasing headache, drowsiness, blurred vision, and confusion is well recognized. Not nearly so much is heard about the same condition in infants, although according to Ingraham and Matson¹ it is common during the first two years of life and the source of a high morbidity if it is neglected. These authors have presented a detailed analysis of their experience of nearly a hundred cases treated in one hospital, and comment upon "the existence of a much larger number of these damaged children than is generally realized, many of whom might be spared with proper treatment." Their paper makes it clear that this must indeed be so, although attention has already been drawn to the subject by several articles which have appeared in the last decade, and although Ingraham and Heyl² in an earlier paper noted that the frequency with which subdural haematomas are found in infancy is largely proportional to the intensity with which they are sought. An injury is usually the first cause, but it need not be severe. In about a third of the cases reported the injury had certainly occurred at birth, and in many more it probably had. Although this is so, a fracture of the skull is not often found, for the infant's skull will distort so greatly without bony injury. The injury that will cause subdural haematoma is of course associated with distortion of the cranium and its structures—distortion which results in tearing of the tributary veins that run into the superior longitudinal sinus and so causes the bleeding which starts the abnormal process. It is for this reason that the haematoma is more often bilateral than not. The kind of injury inflicted to the head at birth is conducive to such tearing of veins. Nearly a half of the children in Ingraham and Matson's series had evidence of infection elsewhere in the body, usually in the respiratory tract, but this was simply the result of their poor general condition, for the prime cause of the illness had not been recognized early enough.

It is most important to appreciate that there is no clinical picture which is absolutely characteristic of subdural haematomas in infancy. It is even more unfortunate that the symptom pattern may be identical with that of many other slowly progressive conditions, for intracranial disease in childhood so often gives rise to such general symptoms as a raised temperature, vomiting, irritability, and failure to develop or gain weight. The commonest

symptoms of a subdural haematoma in childhood are fits, vomiting, irritability, and those of an associated febrile illness. Fits and vomiting occur in over a half, and the fits are quite indistinguishable from those seen in other childish illnesses. The symptoms were present for less than a week before admission to hospital in a third of Ingraham and Matson's series of cases, but in another third they had persisted for over a month. The signs of the haematoma are an increase in muscular tone with increased reflexes, an irregular or raised temperature, and in a quarter of the cases a rather large head the shape of which is not that of hydrocephalus. There may be a cracked-pot note on percussing the skull, and bulging of the fontanelles. Optic atrophy or, very rarely, papilloedema may be seen. The authors say that the condition should always be suspected when an infant who has been through a difficult delivery fails to do well in the first month of life, is irritable, has an irregular temperature, and seems to have rather too large a head. Neither the laboratory nor the x rays help in diagnosis, which never becomes accidentally apparent to the casual examiner, but which can be established only by puncture of the subdural space. Fortunately this procedure is simple and certain, and can be carried out under a wheal of procaine. Ingraham has the infant well wrapped up and gives it a teat with a little glucose to suck. He inserts a fine, short lumbar puncture needle with a stylet into the middle of the frontal suture on each side, under rigid aseptic conditions. The technique is described in detail. When blood is found simple aspiration will not suffice, for the inelastic membrane which remains impedes the normal rapid growth of the infant's brain. It is, however, undesirable to remove the clot by immediate craniotomy, for the child is usually too ill. It is best to aspirate repeatedly until the symptoms have subsided, and when the child's condition has improved sufficiently a large osteoplastic flap can be turned and the clot be removed, capsule and all. The results seem to be excellent, for more than three-quarters of Ingraham and Matson's operated patients not only have remained free from symptoms but have shown normal behaviour and development for their age. It is distressing to consider how very easily a subdural haematoma can be missed in infants, for its effects are serious. Now that its existence has been verified in so many cases it should be recognized with increasing frequency.

TESTS OF LIVER FUNCTION

There is a fascination about the measurement of human functions. Evidence of this is seen in the vast amount of work done on tests of human intelligence, cardiac efficiency, and renal and hepatic function. All this work is inspired by the belief that once we can measure a thing and express the result in figures we are at the beginning of science. This is true, however, only if we know just what we are measuring. We have perhaps arrived at that stage in intelligence testing, and have relatively simple tests that can be applied to individuals or groups by a well-trained technician. So far as concerns the kidney, the measurement of the clearances of inulin and diodrast allows us to make legitimate deductions about the rate of filtration through the glomeruli, the renal blood flow, and the work

¹ *J. Pediatr.*, 1944, 24, 1.

² *J. Amer. med. Ass.*, 1939, 112, 193.

of the tubules; at the same time, however, the tests have become too elaborate and time-consuming for routine use on patients. Neither of these stages has been reached in the measurement of hepatic function, but progress is being made on the road.

Different functions of the liver have in turn attracted attention. Twenty years ago interest was concentrated on the serum bilirubin, and this interest has now been revived by the technical developments associated with the names of Evelyn and Malloy and by the use of bilirubin excretion tests. Nevertheless, the hope that modifications of the van den Bergh reaction would be of value in the differentiation of different forms of liver disease has been generally abandoned.¹ Nowadays we pick our test of liver function according to the object we have in view. If we wish to control a particular hazard in industry or in therapy, as, for example, the risk of liver damage from arsenical treatment, the serial repetition of a single test such as the serum bilirubin or the hippuric acid synthesis may be adequate. In the differential diagnosis of a case of jaundice, and more particularly the decision whether it is due to obstruction in the outflow of bile or damage to the parenchyma, it is desirable to apply a battery of tests. In an article elsewhere in this *Journal* MacLagan recommends the colloidal gold and the phosphatase tests, followed if necessary by the galactose tolerance. Although experience with grouped tests in this country has shown the help they can give in diagnosis, their limitations must be realized. American workers have had an opportunity to use them on a large scale during the recent outbreak of hepatitis after yellow fever vaccine.² In many of the more protracted cases there was no evidence of disturbance of any function of the liver except the excretion of bile. Presumably the damaged cells had regenerated, but adequate connexions had not yet been re-established between the lobule and the portal tract. It would be misleading to call this condition obstructive jaundice in the ordinary sense. Finally, the clinician may wish to exclude hepatic disease in the investigation of ill-health, and Higgins and co-workers³ have shown that chronic disease of the liver is unlikely to be present if the serum bilirubin and the plasma proteins are normal.

All this is empirical, and the clinical scientist will ask how the tests help him in understanding the morbid physiology of hepatic disease. To what extent are the different tests correlated together? Is a high phosphatase value due to the disturbance in the absorption of calcium because the bile is not flowing into the intestine, or is it due to a disturbance in the synthesis of glycogen, which occurs by a process of phosphorylation? Correlations of this kind have not yet been worked out, but we do appreciate the relation between the liver and the serum proteins. The serum proteins undergo quantitative and qualitative alteration when the liver is diseased, and the results are every bit as important as in nephritis. In chronic liver disease, notably cirrhosis of the liver, the serum albumin is generally reduced, whereas the serum globulin is normal or increased.⁴ The degree of reduction in the level of serum albumin seems to be correlated with the prognosis as to the duration of life, with the clinical course of the disease, and with the appearance and disappearance of ascites. There is apparently a defect in the synthesis of serum albumin, and though these patients are able to absorb and retain protein they are unable to convert it into serum albumin. In acute hepatitis the change in the serum proteins is more of a qualitative than a quantitative nature, and it may be better demonstrated by one of the flocculation tests than by the simple chemical analysis of

the serum proteins. There is a shift to the right in the protein pattern with an increase in the gamma globulin.⁵ At present we do not understand why changes in the serum globulin occur in disease of the liver, though it seems as if the increase in the largest molecular weight protein, the gamma globulin, is an effort to compensate for the decrease in the smallest molecular-weight protein, the albumin.

BIRTH UNDER HYPNOSIS

Hypnosis as a means of producing a state of relaxation in which minor operations can be performed has been described but has never become popular. It has been most used in dentistry, but only to a very limited extent. A recent paper from America on the use of hypnosis in childbirth may give added interest to a matter which is of both practical and theoretical importance. Kroger and deLee⁶ report on twelve cases in which practically the whole of labour was carried out whilst the patient was rendered analgesic and trance-like. It seems that the dissociated condition lasted while forceps were applied. Episiotomy and perineal repair were undertaken, and though the report is not clear it seems that hypnosis was used in other cases in which labour was normal. When it was decided to use this method the gravida was placed in a hypnotic condition by the usual suggestive measures at fortnightly intervals from the sixth month onwards. In the course of these sessions deep hypnotic states were produced, and suggestions that the labour would be painless and convalescence normal were made. During labour itself the hypnotic state was produced shortly after onset, and was continued for as many hours as necessary, during which time the patients were able to micturate, defaecate, and bear down as in labour without any hypnosis. The hypnotist could arrange that the suggestions were equally effective if made by the house officer or nurse in charge. It is claimed that to dispense with medical hypnotics and anaesthetics is of much importance where complications such as heart disease or hypertension are encountered, and that in perfectly healthy women the absence of medicine is of benefit in the puerperium.

Why, it must be asked, is the practice not more widespread? Would not suggestions made under hypnosis during the latter months of pregnancy benefit many women frightened of childbirth? The efficiency of modern anaesthetics and hypnotics, and their rapid effects, obviously appeal more to obstetricians, who are still unable to state the exact moment when labour will begin. There is a vigorous conception that the healthy normal mother does not expect to be relieved of labour pains which she knows her friends and her ancestors have experienced and largely forgotten, and there is a sort of superstitious belief that the woman who really fears childbirth is a poor specimen, and that to experience such ordeals is a stimulus to character formation. But the obstetrician rightly fears labours more in the neurotically affected and in those with systemic disorders. If hypnosis does what Kroger and deLee claim, should it not be available for these patients?

The real difficulty is probably a practical one: hypnosis suddenly attempted in the maternity bed will be unlikely to succeed. It must be prepared for by preliminary sessions, and that means a regular time-table for the hypnotist and his availability when labour starts. Hence further trials will come from special gynaecological units to which psychiatrists with interest in the problems of hypnosis are attached. But the evidence that such collaboration between

¹ Stein, H. B., *S. Afr. J. med. Sci.*, 1941, 6, 104.

² Turner, R. H., *et al.*, *Ann. Intern. Med.*, 1944, 20, 193.

⁴ Post, J., and Patrick, A. J., *Bull. N.Y. Acad. Med.*, 1943, 19, 815.

⁵ Gray, S. J., and Barron, E. S. G., *J. clin. Invest.*, 1943, 22, 191.

⁶ *Amer. J. Obstet. Gynec.*, 1943, 46, 655.

the gynaecologist and the psychiatrist is overdue is daily apparent to both parties. The former is wanting to use the latter for many more purposes than to tell him when termination is justified on psychiatric grounds. Both are interested in the amenorrhoea which accompanies anorexia nervosa. Both are interested in the problems of functional dysmenorrhoea. Neither has solved the psychological problems of the menopause or its endocrine substratum: why is the menopause so physically and psychologically disturbing in some, so comparatively minor an event in others? Both psychiatrist and gynaecologist (as well as the sociologist and anthropologist) are interested in a fuller explanation of the food fads of pregnancy, the recurrent fears about mutilated, malformed, and defective children that the pregnant mother has, and about the reasons given for family limitations. When psychiatrists are more numerous and more trained in field work some of these problems may be tackled and suitable prophylaxis undertaken, as well as more use made of hypnosis as a substitute for anaesthetics and medication.

PENICILLIN IN BACTERIAL ENDOCARDITIS

With every new advance since prontosil in the chemotherapy of bacterial infections the question has soon been asked, Will this drug control subacute bacterial endocarditis? Of all streptococcal infections this is the most heart-rending and the most conducive to even desperate therapeutic adventures, for the patient is almost certain to die, and yet there remain weeks or even months for the fullest trial of any form of treatment which has even the faintest hope of success. The advent of penicillin has raised such hopes anew, and requests for supplies for the treatment of subacute bacterial endocarditis have been numerous. It should therefore be generally known that in fact the penicillin treatment of this disease has, on the whole, been disappointing; for this reason bacterial endocarditis was explicitly excluded from the list of conditions for which the present limited civilian supplies may be used. These will probably prove inadequate, until they are greatly augmented, for the treatment of all cases of life-endangering infections which are known to respond well to the drug. If the treatment of a case of bacterial endocarditis means that another patient with taphylococcal septicaemia has to go without it, it is clearly unjustifiable.

The published evidence is as follows. In the second series of miscellaneous cases treated at Oxford, described by Florey and Florey,¹ one patient with subacute bacterial endocarditis was assiduously treated for a whole month on several systems of dosage, including injections at intervals of only one hour, the total dosage being no less than 4,670,000 units. The blood was temporarily sterilized, but relapse with renewed bacteraemia followed cessation of treatment, and the streptococcus responsible became penicillin-resistant. In the first large series of miscellaneous cases reported from the U.S.A.,² penicillin was given to 21 with subacute bacterial endocarditis: 4 patients died, no effect was obtained in 10, 3 improved temporarily, but 2 soon relapsed. Some of these patients probably received inadequate doses. In several later reports from the U.S.A. the findings are somewhat conflicting. W. E. Herrell³ treated 4 cases, achieving only temporary improvement in all. M. H. Dawson and Gladys L. Hobby⁴ treated 5, of which 2 were failures:

1 patient was improved, and 2 were alive and well thirteen and nine months later. The only really encouraging results are those of L. Loewe and his colleagues,⁵ who treated 7 patients in all: 2 of these were atypical in that the organisms concerned were a pneumococcus and a haemolytic streptococcus, but the remaining 5 were examples of *Str. viridans* infection in valves damaged by previous rheumatic disease. After intensive sulphonamide treatment, which apparently failed, they were given penicillin in large doses—usually 200,000 units a day, with a total dosage of over 7 millions in 2 cases and 6 millions and 3 millions in 2 others, combined with 200 mg. of heparin daily. All these patients apparently recovered, but the interval which had elapsed at the time of writing was only two or three months in the majority. A brief statement of the present condition of these patients, now that a further eight months has elapsed, would be a useful contribution to our knowledge of this subject.

Even granting that penicillin may cure a substantial proportion of patients if used in this way, the treatment is a serious undertaking with a considerable risk of its own, and may use up enough of the drug to cure half a dozen other patients with almost equally dangerous, but more susceptible, infections. The subject clearly calls for more extended study on a research basis before a decision on its merits can be reached. Meanwhile only an improved supply position—such as we hope to see shortly—can justify the general release of penicillin for this purpose.

AID FOR RETURNING G.P.s

In the *Supplement* to our issue of Aug. 19 there appeared a letter from a general practitioner who proposed that a fund of at least £100,000 should be raised to assist colleagues returning from the Services to re-establish themselves in practice. On reflection, it appeared to be unwise to start a new fund, designed to make, for general practitioners only, very much the same provision as is already made by the Medical War Relief Fund for the profession as a whole. The author of the letter, on being informed of the activities of this Fund, readily agreed that his suggestion was unnecessary, and asked that his donation of £100 might be paid into the Medical War Relief Fund. A similar request has been made by a woman practitioner, who, prompted by her colleague's letter, had sent a contribution of £50. There may be other doctors who are not well acquainted with the work of the Medical War Relief Fund. The honorary secretary of the Fund will gladly answer inquiries addressed to him at B.M.A. House, Tavistock Square, London, W.C.1. The Committee of the Fund would greatly appreciate the co-operation of members of the profession in making the Fund known to colleagues or dependants of colleagues who, though eligible for aid, may be unaware of the Fund's existence.

As announced in last week's *Supplement* (p. 56) the postponed Annual Representative Meeting, 1944, is to be held in London early in December, subject to the exigencies of the war situation. It will open at B.M.A. House on Tuesday, Dec. 5, at 2 p.m., and is expected to end on Friday, Dec. 8, though it will continue until the business is concluded. The Annual Conference of Local Medical and Panel Committees will open at B.M.A. House on Thursday, Nov. 2, at 10 a.m., and will continue if necessary on the following day.

FRACTURES OF THE CARPAL BONES

BY

H. A. HARRIS, M.A., M.D., D.Sc.

(Anatomy School, Cambridge)

The interesting analysis of "Fracture of the Carpal Scaphoid" by Robertson and Wilkins (1944) permits the mere anatomist to call attention to the need for still further sorting. In the series of 158 wrist-joint injuries in young adults, 100 cases of fractured scaphoid occurred. There is one enigma in their analysis, for, of 100 cases of fractured scaphoid, they state that 70 united but 72 resumed full duty. What was the nature of the full duty in the two who resumed with ununited fractures? This is important, for in most cases of ununited fracture of any bone of the carpus in man and domestic animals the end-result is a generalized osteo-arthritis of the wrist. Yet another omission in the analysis is the failure to ascertain with certainty how many of the remaining 38 cases of "sprain" of the wrist really had a fracture of some bone other than the scaphoid.

Fracture of the styloid process of the ulna often complicates Colles' fracture, and sometimes accompanies fracture of the scaphoid. It is, however, the flake fracture of the dorsum of the cuneiform (triquetrum) and os magnum (capitatum) which is so often missed radiographically. The fracture usually occurs during a fall, or recovery from a fall, with the wrist in full pronation and extreme flexion. The detached flake is torn off during extreme tension on the dorsal radio-carpal ligament, which runs downwards and medially from the radius to the dorsal surfaces of the scaphoid lunate, and cuneiform bones. The deeper fibres of the ligament, on the ulnar side, run to the cuneiform bone and blend with the articular disk of the ulno-carpal joint. The flake fracture probably occurs more frequently in the cuneiform than in the os magnum. This flake fracture is easily missed on both antero-posterior and lateral radiographs. It is rendered visible only on that lateral view which places the area of maximal pain as near the periphery as possible (see Fig.)

Lateral radiograph showing flake fracture of the cuneiform (triquetrum) bone

Another rare type of fracture is that of the pisiform bone. The fracture involves a flake on the distal tubercle, at the attachment of the pisohamate and pisometacarpal ligaments, which are often wrongly regarded as continuations of the tendon of the flexor carpi ulnaris.

Multiple injuries at the wrist are a common feature in falls by women laden with shopping baskets and in stokers and coal-miners who "catch a crab," such as a bolt head or nut when using a shovel on a steel floor. One case showed this series of complications in a manner not to be forgotten. The patient had fallen while carrying a parcel in each hand. The first doctor recognized the obvious Colles' fracture, the surgeon at the hospital also saw the fractured styloid process of the ulna, his radiographer spotted the fractured scaphoid, and a certain anatomist discovered the flake fracture of the cuneiform. All were eventually very pleased with themselves, and the patient was put up in a magnificent plaster cast. Two days later he returned stating that the maximal pain was not in the wrist but in the chest. Two fractured ribs were recognized—but essentially by the patient. Thus, in any fall involving an injury to the wrist, not only must multiple fractures in the neighbourhood of the wrist be considered, but it is also worth while giving the patient's chest a gentle squeeze from front to back and from side to side—a manoeuvre which uncovers a fractured rib much more rapidly than a radiograph.

A comparison of the wrist of man with that of a reptile, such as a crocodile, shows that in the lower forms the ulna is much stouter than the radius, whereas in the primates generally, and man in particular, the radius is much stouter at its distal extremity than is the ulna. The strength of construction of the hand in man is concentrated in the radius, thumb, and index and middle fingers. In the reptile the strength of construction is centred on the ulna and the third and fourth metacarpals. Conversely, however, the carpus in man has signally failed to respond to this change, and the narrow-waisted scaphoid is too delicately formed for the load which is thrown upon it, especially in radial abduction. Moreover, one radial carpal element, the os centrale, is missing in man, gorilla, and chimpanzee, thus further reducing the bony architecture of the radial side of the carpus. On the other hand, the reptilian carpus has a strong solid, rod-like scaphoid. If one could transpose the reptilian scaphoid to the human hand the wrist might be rendered much more stable, but at the cost of those movements of adduction and abduction, as well as supination, so essential in cutting up food on the plate and transferring it to the mouth.

The scaphoid is the most irregular and variable of bones in the carpus both from the point of view of comparative anatomy and from that of individual variation in man and the primates. The scaphoid may be absent as reported by Botreau Roussel (1922) or only partially developed, as in the case recently reported by Hodgson (1944). It is the most variable in the child as regards the time of appearance of the centre of ossification, and it may occasionally precede or more usually follow the appearance of ossification in the trapezium and trapezoid. Again, in the individual it varies considerably as regards dimensions in association with a heavy or a slender wrist, and it varies in particular in its proximo-distal thickness. It varies also as regards the development of the anterior tubercle and the posterior transverse ridge, and this in turn decides whether the waist of the bone is more or less marked. The anterior tubercle develops in proportion to the thickness of the anterior annular ligament (flexor retinaculum) of the wrist and the bulk of the short abductor pollicis muscle. The posterior transverse ridge varies essentially with the development of the radio-scaphoid and dorsal carpal ligaments, as these ligaments sometimes form a transverse gutter rather than a rough ridge on the bone, between the proximal articular surface for the radius and the distal surface for articulation with the trapezium and the trapezoid. One might almost say that there is a particular anthropological type in which fracture of the scaphoid is more apt to occur.

Fractures of all the other bones in the carpus are occasionally seen, but the frequency of flake fractures in the cuneiform and os magnum, and their omission in most modern textbooks, is such as to justify the application of a good comfortable plaster cast to any sprain of the wrist accompanied with pain on movement.

Observation and Common Sense in the Student's Training

SIR,—Twenty-five years as a teacher—however inefficient—of medicine, and fifteen years as an examiner—however inadequate—should entitle one to presume, through this dual experience, a qualification to venture some observations upon the subject of Dr. Ff. Roberts's entertaining article (*B.M.J.*, Aug. 26).

I am whole-heartedly in agreement with Dr. Roberts's suspicion that there is something about the system of medical education which suppresses such powers of observation as the student naturally possesses. I am confident that the average medical student easily surpasses in native ability and mental equipment the average of the population of his age and social position. The defects in his methods of application when he appears for his final examination will be explained by all conscientious examiners as dependent upon the imperfections of his education, more especially as all examiners are themselves teachers.

From the moment that he enters the wards until the moment that he safely navigates the shoals and quicksands of Queen Square (or its equivalent) he is confronted with obscure pathological material and rarely the trivial or commonplace, because the subjects selected for admission to hospital are as a rule either seriously ill or afflicted with conditions of complexity or difficulty which demand elaborate investigation. It is not surprising, therefore, that he tends to acquire a distorted impression of the practice of his profession which is going to occupy the whole of his working life, and this frame of mind is fostered by the character of his final examination.

His teachers are obsessed, or at least unduly influenced, by the necessity to produce not efficient practitioners but qualified medical men, and their approach is adjusted to the demands imposed by examinations. Dr. Roberts repeats the well-known instance of failure to recognize an artificial eye. But the circumstances of his education justify the student in expecting that the failure of a pupil to react must necessarily be viewed in the light of a pathological lesion. He is in the position of the jailer who cannot imagine that anybody in the dock can be innocent unless he is guilty of some crime or other, what is he doing there? I have often been tempted to produce for the clinical examination a number of perfectly healthy subjects in order to see how many candidates would have the courage and confidence to assert that they were unable to detect any lesion.

It is the atmosphere we create in our clinical instruction which inhibits the common-sense approach and leads to the logically expressed criticism that the powers of observation of the average medical graduate are "relatively undeveloped." Over and over again in a question to a class on an issue of common sense my appeal has been met with silence until I have issued the invitation to forget that they are medical students but to answer as ordinary men in the street. And invariably the correct response is forthcoming. There is learned talk of future education in psychology, in social medicine, in psychosomatic medicine, as if these are to be additional bucketfuls in the ocean of instruction to which the student has already to submit, instead of a general principle which should underlie every circumstance and detail of his training. No doubt I shall be reminded that the out-patient department should provide this method of instruction in *excellis*. So it should, and so it can, but how rarely is this achieved! The circumstances under which such practice is necessarily conducted afford great difficulties to even the most enthusiastic and energetic out-patient physician intending to combine attention to the sick with undergraduate instruction. It is clear, moreover, in what light such trivial or relatively uninteresting conditions which possess the minimum of examination value are generally held, when this work is entrusted to the most junior members of the staff, who have to accept this apprenticeship as a preliminary to promotion to the wards. True, there has to some extent been a move to demand both in-patient and out-patient attendance from all members of the staff, but

the most logical application from the point of view of efficient instruction would be promotion in the reverse direction, entrusting the out-patients to the most senior and experienced.

I have mentioned the nature of the final examination in influencing the character of clinical instruction. May I be permitted to enumerate a few examples of the type of question which I have thought appropriate to test the ability of a candidate and assess his suitability to begin the practice of his profession and employ the knowledge he possesses?

What is the significance of pallor?

What can be learned by a visual examination of the nails (or the tongue, or the sputum, or the stools)?

How would you investigate a complaint of tiredness in a man of 45?

What are the commonest causes of headache in a child of 10 years of age?

I know that this is not the type of question that is popular with examinees. The answers are not to be found conveniently arranged in any textbook of medicine. They cannot be dealt with by selecting and putting on the appropriate gramophone record. Nor, it must be admitted, are they particularly popular with fellow-examiners, who naturally prefer to run the eye rapidly down a column to see if the essentials for a pass are present rather than plod wearily through material, generally illegible and more or less unreadable. No wonder one sees the preponderance of the stereotyped request for the causes of haemoptysis, the treatment of gastric ulcer, the signs and symptoms of this, that, or the other condition.

Was it Talleyrand who said that a good doctor should know a little about everything, even medicine? This, I suppose, is really what is nowadays interpreted as social medicine. I have the impression that those of us who started 35 or 40 years ago mixed more freely with our patients. Perhaps we had more leisure to observe; perhaps we were less overwhelmed by the complexities with which the modern student is obliged to contend. I used to wonder why some of my contemporaries, utterly undistinguished academically, were so successful in practice. But now I cease to wonder. They had spent their time to advantage in learning a little about everything, even a little medicine.

Dr. Roberts pleads for a revolution in medicine. I am sure he is right, but I wonder who have the knowledge and the authority to reconstruct the curriculum and to choose the right type of teacher, one who combines adequate knowledge with a correct clinical approach. I have heard of a physician to a teaching hospital who refuses to see any patient under his care unless and until his house-physician has obtained every possible pathological and radiological examination. He is then prepared to shuffle a pile of reports and deliver an opinion. It seems unnecessary that he should see the patient at all. Imagine the devastating damage that such a procedure does to his clinical clerks. This is an exceptional example, but the principle is reproduced to some degree only too often in teaching schools.

It is difficult to define what it is easy to recognize. Many of us can see the imperfections of a system while unable to reconstruct. We are inclined to babble about the importance of first principles in training, after which the further instruction of the general practitioner or the production of the specialist would be a comparatively simple matter.—I am, etc.,

London, W.1.

ADOLPHE ABRAHAMIS.

Limitations of Current Medical Training

SIR,—The article by Dr. Ff. Roberts—and the previous one in the same strain by Sir Walter Langdon-Brown, to which Dr. Roberts refers—have emphasized a state of affairs which has exercised my mind a good deal during these war years—namely, the training of the new entry in our profession. Having retired from practice before war started, and been out of touch with students and junior practitioners for some time before that, I have been startled and much disturbed by the limitations of current medical education as exhibited by the young doctors whom I have met in E.M.S. and other public hospitals since war began (when I returned to harness). The modern trend to specialization is, no doubt, inevitable, owing to the complexity of scientific medicine and surgery nowadays; and it should be beneficial if properly controlled. As things are, however, the

new generation, in my view, specializes at far too early a stage, and undertakes to become an expert in some branch of our art long before any real knowledge of medicine or of human nature has been gained. The result is a great number of pseudo-specialists, many of whom openly boast of knowing nothing outside their specialty, in fact, they are in many cases grossly ill equipped to practise even that. Unfortunately those who remain in general practice are only too prone to refer all except the most trivial cases of illness to one or more specialists, whose verdicts are accepted as if they were oracles from heaven, without critical examination of any kind. Since many of these self-styled 'specialists' are ill educated, the most grotesque errors of diagnosis and treatment are liable to be perpetrated.

But this is an earlier stage than this at which clinical teaching seems to me to have taken a wrong turning. The student is brought up to believe that diagnosis can only be made in the pathological laboratory and the x-ray room. Every new case in a teaching clinic is at once subjected to eight, ten, or a dozen pathological tests, nearly all of which are superfluous. Instead of using laboratory findings as aids to, or checks upon, diagnosis, after a thorough and full investigation of the physical signs, the modern student never learns anything about the latter, but relies entirely on a series of reports from these special departments. Observation of the patient is so cursory as to be non-existent. The elicitation of physical signs is fast becoming a lost art.

I once saw two consecutive cases of lobar pneumonia in the same ward in which the consolidation was diagnosed on the wrong side. What had happened, I suspect, was that the diagnosis was made on laboratory findings. Being incapable of learning anything from percussion because he had never been taught the proper way of doing it, and not observing that one side of the chest was immobile whereas the other was working over time, the R.M.O. mistook the suppressed breath sounds of a solid lung for the normal, and the exaggerated vesicular murmur of the unaffected side for bronchial breathing. To complete the story, the patients were dosed so immoderately with sulphapyridine that both developed lung abscess and died.

Nor is this a highly exceptional case. In many hospitals practically every case of pyrexia, even when clearly due to an abscess, is at once subjected to sulphonamide treatment, quite regardless of whether this is indicated or not, and this drug treatment, even when it is likely to be beneficial, is often pressed to absurd overdosage. When penicillin is made widely available I expect to see just the same sort of indiscriminate misuse of it.

As for the diagnosis of cardiac disease, for all the effect James Mackenzie has had on the young generation (and therefore, presumably, on their teachers) he might never have existed. Very few of the junior members of the profession think of ascertaining the position and character of the apex beat, the size of the heart, the regularity of its action, or its functional efficiency. Murmurs are their sole criteria of cardiac disease, usually misinterpreted at that. Quite recently I saw a woman in her sixties perfectly able-bodied and free from all symptoms of (physical) disease. Eight years ago she was examined by a young doctor who is well thought of by some of his seniors. He then diagnosed mitral regurgitation, mitral stenosis, and aortic stenosis (she was equally free from symptoms then). She has, in fact, an apical systolic murmur due almost certainly to atheroma, and no other abnormal sign of any description whatsoever. Mitral stenosis, more than any other valve lesion, is diagnosed about four times as often as it exists.

I am sure that the fault lies mainly with the clinical teachers, who demand of their residents all kinds of irrelevant pathological reports on every case, the latter accordingly get into the habit of having even more laboratory reports ready for their chiefs when they come, so as to be able to anticipate every requirement. The students in attendance naturally think no diagnosis is possible without all this expensive and time-wasting redundancy. I know of a case where a resident, confronted with a simple dislocation of the jaw, sent the patient a considerable distance in a car to an x-ray clinic (thus wasting time, petrol, and a film) for confirmation of the diagnosis. On the return journey the dislocation reduced itself in the car.

No so long ago I put these views to two pretty senior teachers at two different medical schools. One said, "Well, if you

saw, as I do, the mistakes made in general practice for want of an elementary laboratory report, you wouldn't wonder at my impressing on my students the need for this assistance." The other said, "I find the laboratory reports are more often right than my diagnoses based on physical signs." Both these answers beg the issue: they are virtually an abdication of the function of the physician, which is to use every method of investigation to establish the diagnosis and direct the treatment. Laboratory reports should be only part of the investigation of a case, not the whole of it, as the new entry are being taught to believe. It is perhaps not necessary to stress the wasteful extravagance of repeated and unnecessary laboratory investigations—and my experience in hospitals leads me to believe that quite seven out of eight are unnecessary. I will just end by saying that I can show anyone who likes to see her a patient who has had no fewer than 263 blood counts done—I have seen that number of reports, and the pathologist tells me that there were in fact many more, about 400 altogether, he thinks, she is no better now than she was before the series began—nothing has been learnt that has been of any help to diagnosis or treatment. She is, I fear, a typical example of the most up to date methods of medical science—I am, etc.

HENRY ROBINSON, M.D.

The Road to Positive Health

SIR—I am one who has lived during fifty eventful years of history, and more than half of them as a general practitioner. During that time advances in knowledge, particularly in the fields of science, have been remarkable, and ever the pace quickens.

Looking around and back I am fain to ask myself, How is it that the difficulties of life still multiply, that the mists of confusion appear ever thicker and thicker? How is it that a true philosophy of life grows more remote? The ignorance, class hatred, bitterness, vice, the misery, the squalor and wretchedness of so many homes, all these things that I have witnessed, how is it that these still abound, even in this supposedly enlightened country? How is it that after two thousand years of so-called Christianity the unspeakable horrors of the present and the last wars, with cruelty unsurpassed in the world's history, should still be possible among civilized men? How is it that in the world of to-day there exist as many inherent evils, monsters, imbeciles, and perverts of every sort and kind as there were before the birth of Christ?

How is it that such musings can make all the poetry of literature, of music, of colour to appear as but the mocking diversions of unreality? The answer that I find is that man is master or would-be master of all things but himself, that he has devoted all attention to his surroundings and but little or none to himself or the fundamentals of his origin. In every walk of life, the medical not excepted, modern trends and training have produced a plethora of able technicians, but they are responsible, too for a veritable dearth of stylists. If the question were asked, What is the profession of the doctor? ninety nine out of a hundred answers would be, The treatment of the sick. The pages of your *Journal* Sir are filled with the endless pursuit of, the latest contrivances for dealing with, the disease enemies of mankind. With the passing years of the physician's practice the conviction grows that, however great the absorption of the mechanic in the repair of broken down machinery, or the joy of the restorer in his own ingenuity, yet, inasmuch as treatment or even cure is not prevention, and the machine is but a machine in part, the theme is not based on ultimate causative factors, and practice therein is bound to eternal frustration, and may even defeat its own ends. When this is accompanied by such reflections as outlined above, then indeed a sense of utter futility may impose itself. Doctors will agree that the definition of their work is altogether too narrow, and that experience leads to a knowledge of people and a philosophy of life which is both wide and deep. Yet that knowledge is seldom publicly voiced and even less often with more than the weight of isolated individuality.

The introduction of a national medical service, always provided that the doctors escape political subversion, may enable the profession to make its voice heard, as it has not been heard hitherto, in the councils of the nation, and to join in

shaping the eugenics of the race, using the term in its widest sense. Will the opportunity be taken? In the years immediately to come this country and the world will have need of all the collective wisdom of its wise men if it is to build anew and better upon the years of suffering and of human degradation. Among these counsellors the doctors, speaking as an influential and united body, should surely be found.

All the implications of positive health—and I appeal to my colleagues to reflect thereon—if probed to their ultimate foundations, will be found to extend far beyond even those premisses in the British Medical Association report. In my belief acceptance of those implications would herald in a fullness of breadth and splendour a reorientation of the ethics of medicine.—I am, etc.,

E. D. BROSTER.

Specialties and Diplomas

SIR,—There is so much in Dr. Walshe's stimulating article on higher or postgraduate studies in your issue of Sept. 2 which commands assent that I hesitate to appear in any way critical of his views. However, I do not think that he is right in his advocacy of the segregation of certain specialties, nor do I think he presents the case for and against postgraduate diplomas quite fairly. In regard to the first point, he advocates that "neurology, dermatology, paediatrics, etc., should be pursued methodically in adequately staffed and equipped special hospitals and schools." I cannot help feeling that Dr. Walshe's favourable view of such a system in general is based on a particular example. The success of the National Hospital for Nervous Diseases in relation to the ideals at which we aim will be generally accepted. The reason for this success may perhaps be attributed to the fact that neurology is a well-defined branch of medicine, and in that the precision of its methods and the conclusions of which it is capable have attracted many of the best intellects in the profession. Whether this hospital could have benefited medicine as a whole even more than it has if they who there studied structural change in the nervous system had been more closely associated with those concerned with disorders of its functions is a matter of opinion.

To put dermatology on the same footing as a specialty is open to question. The dermatologist is more often than not considering a surface manifestation of a deeper disease, and to segregate the treatment and study of such conditions can no more be expected to further progress than if we were to establish, say, a special hospital for all those suffering from a limping gait.

Paediatrics, it seems to me, should certainly be studied in a general teaching hospital, unless these are to be entirely masculated and yet remain responsible by virtue of their organization for a large proportion of early postgraduate training.

What Dr. Walshe's "etc." contains is a matter for speculation. If we refer to thoracic and rectal surgery, and orthopaedics are to be included under this heading, I would submit that these subjects are but subdivisions of general surgery and that progress and education in medicine will be best served if they form sections of a general teaching organization. Dr. Walshe's statement, "The one or two men staffing the small special department must perforce work in comparative intellectual isolation," may be true of some existing organizations in our smaller teaching hospitals. The remedy is not to isolate them further in special hospitals, but to extend their sphere of activity and ensure contacts of their staff with workers in all branches of medicine. If a teaching unit as recommended by the Goodenough Committee controls at least 1,000 beds (chap. 3, para. 27), it will be possible to provide staff and adequate in- and out-patient accommodation for most of the recognized special subjects. The success of the Mayo Clinic in many fields of postgraduate teaching and research may be put forward as an example of the value of the mutual contacts and discussions which it has made available to members of all branches of the foundation.

In his assessment of the disadvantages of postgraduate diplomas Dr. Walshe does not consider the oldest and best-established of these based on the earliest form of specialization in medicine—namely, the F.R.C.S. and M.R.C.P. Both these dip-

lomas are generally accepted as evidence of a man's sound early training in the basic sciences and his subject; few would regard them as more than that. In their present form and conducted by examiners imbued with the right spirit they do ensure a period of study which is a salutary experience and discipline for the majority. Classification by examination has its obvious defects, but preparation for higher examinations takes but a small fraction of the time necessary to the training of an individual in the highest standards of medicine. Admitting the advance and need for specialization—and Dr. Walshe does—it is reasonable to suppose that the examinations for diplomas in certain subjects can be so planned that a comparable knowledge of the basic science in relation to the specialty has been required. The further progress of the specialist will always depend on his innate ability and his later opportunities for study.—I am, etc.,

Os.O.d.

C. MAX PAGE.

Refresher Courses for the G.P.

SIR,—Dr. Walshe, in his admirable survey of ideals for postgraduate medical instruction (*B.M.J.*, Sept. 2, p. 297), condemns refresher courses for general practitioners. These, he says, are of little or no cultural value, and their influence is but transient.

This has not been our experience at the Royal Northern Hospital. Practitioners were loud in their praise of these courses; indeed, some of those who attended continue to write to my colleagues and myself of the benefits they received from our refresher courses, the last of which was held five years ago! Many of the doctors went so far as to state that the clinical facilities they were afforded and the teaching they received at the Royal Northern Hospital proved to be of lasting benefit to them in their professional work.

In this connexion I should like to point out the great possibilities of extending postgraduate instruction at the non-teaching hospitals. As opposed to 11,600 beds controlled by the teaching hospitals, the non-teaching hospitals of the British Isles possess 51,000 beds. Furthermore, the out-patient departments of some of these institutions are favoured with clinical material second to none. Again, those interested in this subject can easily verify that teachers are not lacking at these hospitals; indeed, they will find that, owing to an unexplained anomaly almost peculiar to this country, some of Britain's best-known teachers and consultants are relegated entirely to non-teaching hospitals. These facts call for an explanation as to why the non-teaching hospitals had little or no direct representation in the recent conference with the Minister of Health on the subject of medical education and consulting practice.—I am, etc.,

London, W.1.

HAMILTON BAILEY.

SIR,—Dr. Walshe in his article (*Journal*, Sept. 2) doubts the value of short refresher courses for general practitioners. As a general practitioner I agree with him in so far as the short courses run before the war for panel practitioners are concerned. I attended one in 1938 which lasted a fortnight. Looking back on it my criticism would be that a fortnight was much too short a time for us to get back into the academic atmosphere; that it was held in a hospital which was not a medical school; and that the staff of the hospital, who were as keen as we were that the course should meet our needs, were very uncertain of the kind of teaching that would serve this end.

The postgraduate training of a general practitioner who intends to remain in general practice, and who is not seeking a diploma with a view to specializing, should, I think, be on the following lines. The period should be a full academic year. The student should be given appointments with definite if limited responsibilities in the practice of the hospital—as a clerk or dresser in the various departments—and at the same time he should have the opportunity of attending tutorial classes covering the field of medicine in its widest sense. A general practitioner does not need to know the details of surgical, pathological, or other special techniques; but he does want to know what can be done by methods introduced since his student days, and he needs to check and revise the methods he has been accustomed to use. I believe, however, that the most valuable part of a course of this kind would be the rubbing of one's wits against one's fellow students', and the

living again in an atmosphere of active thought. The school to give such training should be specially organized for the purpose—not ticked on to an undergraduate school or to a research institute, nor should it be a school for potential consultants and specialists who are seeking a higher diploma. If it should become possible for all general practitioners to spend one year in ten in such a school the level of medical work would be not only raised but kept high—I am, etc.,

KINGSWOOD BISTOL

N S B VINTER MB

Food and the Nation's Health

SIR—The White Paper has been from time to time criticized for its meagre references to the preventive side of medicine in general, and to that of nutrition in particular. Is it not time that the Ministry of Health should be pressed to give assurances that this fundamentally important problem will be tackled energetically the moment the exigencies of the war allow and that it will be looked upon as an integral part of any health service that may be forthcoming?

During the last twenty years or so a vast amount of information has been acquired showing the close relation between food and health—both physical and mental. It is a humiliating thought that animal breeders have a much keener appreciation of the importance of feeding their stocks properly than the authorities who are responsible for providing the nation's food. The medical profession has been stressing for years the virtues of a wholesome loaf, an uncontaminated milk supply, a fresh fruit and vegetable supply, and other food reforms. The response of the authorities concerned has been far from satisfactory.

To show what can be done in a small way, and in a comparatively short time, I need only refer to the efforts made by the Cheshire Medical and Panel Committee and the Peckham Health Centre to raise the standard of the people's health. To the best of my belief the work of these two bodies has been carried on without any support—financial or otherwise—from the Government or any public authority.

The Minister of Health, with all the resources that he requires at his disposal, has a supreme opportunity now to initiate a long term plan for the reduction of sickness founded on a more rational and natural basis, and at much less cost, than by the methods set forth in the White Paper—I am, etc.,

Tapeworm in Trout

SIR—I have read with much interest the article by Dr Hickey and Mr Harris on the infestation of reservoir trout in Dublin with *Diphyllbothrium* larvae.

In 1944 Duguid and Sheppard recorded a similar outbreak among trout in a South Wales reservoir, but in this case the natural definitive host was not found. Later, an experimentally infected rat was kindly sent to us by Prof Duguid, and material obtained from this animal enabled us to complete the life-cycle of the parasite in another mammalian species, the dog *Coracidia*, which emerged from eggs passed in the faeces of the rat, were fed to *Cyclops* which in turn were fed to the stickleback (*Gasterosteus aculeatus*). The plerocercoids which developed in the body cavity of these fish were shown, both directly and after passage in the pike, to infect the dog. In view of this fact, Dr Hickey's implication that the two outbreaks are similar and that in Ireland at any rate, the gull and cormorant are the definitive hosts, is of considerable interest.

If we are to accept this suggestion, then this particular species of *Diphyllbothrium* which appears to develop equally well in the mammalian as in the avian host, exhibits a degree of specificity which is surprisingly low, even among the Pseudophyllidea. While Dr Hickey's suggestion may be perfectly correct the evidence he produces is insufficient on which to base a statement that the adult tapeworms found in the gull and cormorant have resulted from the ingestion of plerocercoids from the trout for so far as we can ascertain he has as yet made no attempt to support this statement by actual feeding experiments. The fact that Dr Hickey has considered the causative agent of the Welsh and Irish outbreaks to be the

same has apparently been made on the similarity of the plerocercoids from each of the outbreaks. A proportion of the plerocercoids recovered by Duguid and Sheppard were atypical, as compared with those of *Diphyllbothrium laium* showing incipient genitalia and evidence of segmentation. A possible explanation is that the trout in South Wales were infested with plerocercoids belonging to two distinct species of *Diphyllbothrium* one of which develops in the avian and one in the mammalian host.

A full account of the life cycle of the parasite which caused the outbreak among trout in South Wales will be published in the near future—I am, etc.,

Liverpool School of Tropical Medicine

Episiotomy

SIR—In his letter on episiotomy (Aug 26, p 291) Dr H S Gaskell quotes a London postgraduate teacher as saying "Do an episiotomy in all prumps." To me this seems most unfortunate teaching. By all means do an episiotomy where the only alternative is a serious perineal tear, but to suggest that the perineum can never be saved by any other means is to rate our skill pretty low—lower than that of many a midwife.

However the object of this letter is not to criticize but to draw attention to a simple tip which seems to be less widely known than it deserves. Like many good things it is very simple. When the greatest diameter of the head is beginning to stretch the perineum the mother's legs should be fully extended at the hips. I first saw this point mentioned in a short note by Dr W E Fothergill (*Medical Annual* 1921, p 284), and I earnestly commend it to anyone—midwife, practitioner, or even postgraduate teacher—who has not given it a trial. As Dr Fothergill remarked your trousers don't tear when you are standing but when you are bending down—I am etc.

Military Psychiatry

SIR—A very interesting point about the military psychiatry in the Middle East is that if there had been enough transport a large number of men who were sent back to duty and recovered would have been sent back to this country to be discharged from the Service. It would be a great help to older practitioners if the figures given by Col Craige might be transposed into the unofficial classification of the last war, I am particularly interested, because I have had the very unusual experience of acting as M.O. to a mixed unit of Army and Air Force in two wars. In both wars I found a big difference between the two Services. We used to divide the psychological cases into (1) a very small group of genuine diseases such as dementia praecox, (2) a very small group of malingerers—real wrong uns who would deliberately fake a disease, (3) a very much bigger group of "skrimshankers"—men who were making the most of a disability. They saw no reason why they should hurry back to the line, and, anyhow, why should not somebody else take a turn? They were not going back until they were sent and anyhow they were not going on "any bloody route marches", (4) a big group of neurotics the most interesting group was that of the pilots who were firmly convinced that any man who crashed was unfit to fly for the rest of the war. But most of them were the ordinary people who are enormously interested in their health.

If Col Craige would put the modern label to the e groups with the corresponding figures, it would make comparison possible—I am etc.,

Laryngeal Spasm under Pentothal

SIR—I would like to congratulate Dr Philip Ayre on his lucid exposition (Aug 19 p 224) on the role of the anaesthetic agent in relation to the surgeon. Like dermatology, it is not only what is put on that matters but the way it is put on. Believing as I do that laryngeal spasm is an avoidable complication of pentothal anaesthesia, I sincerely think that Dr Ayre

must be so skilled that he has never, perhaps, needed to attempt intubation on a patient with severe spasm. I have tried once. It was a simple short orthopaedic case who vomited and developed spasm following pentothal administration 4½ hours after his breakfast. In this case the false cords were so tightly apposed that intubation was impossible. I dare say a metal tube could have been forced through, but at what risk? Anyway, the patient recovered later with oxygen inflation.

My impression is that once severe spasm has been allowed to develop, nothing can be done until the false and true cords have relaxed. This relaxation unfortunately does not occur until the patient is so anoxaemic that he is pulseless, black, and virtually on the point of death. However, if at this stage the mask is on the patient's face and the anaesthetist is prepared to inflate the lungs a dramatic recovery should occur. In these circumstances intubation is surely unnecessary and a waste of priceless time.

How is laryngeal spasm avoidable? May I, Sir, have further space to attempt an answer to this inevitable question?

1. Atropine helps by diminishing the chance of secretions being drawn on to the larynx.

2. Respiratory obstruction must be avoided during the injection. Even one obstructed respiratory effort may produce a cough and spasm. One so often sees pentothal being injected while no attempt is made to lift the relaxed jaw. Consequently every effort at respiration produces merely a tug on the larynx, and when at last the airway is freed, mucus is drawn on to the larynx, and spasm results.

3. Avoid using pentothal, certainly in large doses, on a patient whose stomach is not empty.

4. Take away at once any irritant, be it cyclopropane, ether, or nitrous oxide, till the spasm has passed, as it will if the irritant is quickly removed. This may cause delay, but it is safe.

5. Give oxygen as soon as the patient becomes dusky. Do not wait till he is blue.

6. Avoid inserting an airway too soon. This may produce gagging and a cough—the precursors of spasm.

7. Avoid attempting intubation on the uncocainized larynx following pentothal alone unless a "knock-out" dose has been given.

Many tragedies have been attributed to pentothal, but I have not heard of one unavoidable death due solely to pentothal when given competently.—I am, etc.,

P. S. A. HEYWORTH,
Fl. Lieut., R.A.F.V.R.

Trilene Anaesthesia

SIR,—I read with great interest Dr. Enderby's excellent paper on trilene in the *Journal* of Sept. 2. Coming, as it does, from one with so wide an experience of this agent it will, I am sure, prove very valuable to all anaesthetists who are in search of authoritative guidance in this somewhat controversial subject. There are, however, one or two minor points in relation to trilene anaesthesia which I should like to mention by way of slight amplification.

It is possible to eliminate the risk of overdosage, so properly emphasized in this article, if the nitrous oxide and oxygen are blown over the surface of the trilene intermittently for 5 out of every 10, 15, or 20 minutes according to the requirements of the patient. This procedure prevents undue elevation of the respiratory rate, which in fact can be used as a guide to depth of anaesthesia, and at the same time does not mar the smoothness of the anaesthetic. I should also like to draw attention to the electrocardiographic studies of the heart's action during the administration of trichlorethylene recently published in America (Waters, R. M., Orth, O. S., and Gillespie, N. A., *Anesthesiol.*, 1943, 4, 1; and Geiger, A. J., *J. Amer. med. Ass.*, 1943, 123, 141). These workers noted the rather ominous occurrence of multiple-focus ventricular extrasystoles.

Trilene is non-explosive and practically non-irritant, and is the best available volatile agent for use in the presence of diathermy. The fact that it cannot produce more than at best light second-plane anaesthesia will, however, sharply limit its usefulness unless the avertin-trilene sequence proves generally satisfactory. Since its action on the cardiac rhythm is still suspect, and the signs of anaesthesia are sometimes misleading, it is doubtful if anything is to be gained by using trilene as a routine adjuvant to nitrous oxide and oxygen instead of ether, except, perhaps, in patients with an extremely irritable pharynx

who will not tolerate ether vapour without violent coughing. Finally, let us teach our students an even healthier respect for trilene than they have for cyclopropane, because of the two the former is probably the more dangerous drug.—I am, etc.,

Manchester Royal Infirmary.

A. R. HUNTER.

Congenital Atresia of the Oesophagus

SIR,—In an annotation in your issue of Aug. 26 you were good enough to refer to my interest in this matter as set out in the Haliburton Hume Memorial Lectures delivered in May of last year (*Newcastle med. J.*, 1944, 22, 1). Some of your readers may like to know that ample justification for my confidence in the surgical management of this condition has been provided by the work of William E. Ladd of Boston, U.S.A., who is so well known for his successful surgical attack on congenital defects in infants. That surgeon has made a notable contribution to this subject, and has recorded 5 successful cases among 34 subjected to operation. An account of his work will be found in a fully illustrated paper published in the *New England Medical Journal* for May 25, 1944 (230, No. 21), entitled "The Surgical Treatment of Esophageal Atresia and Tracheo-esophageal Fistulas."—I am, etc.,

British Postgraduate Medical School,
London, W.12.

G. GREY TURNER.

Service Medicine

SIR,—In my humble opinion it is regrettable that you published in your issue of Aug. 19, under the heading "Service Medicine," a letter from the pen of a correspondent who is anonymous.

So long as the war continues every effort of all the members of our profession, particularly those of us who are privileged to serve the armed Forces of the Crown, should be directed solely to perfecting our methods, both clinical and administrative, of alleviating the sufferings of the wounded and of the sick. Such controversy as your anonymous correspondent would raise cannot contribute to the wartime efficiency of the profession; on the contrary, if your anonymous correspondent really has the following he claims it could seriously impair the profession's paramount and only function during the continuation of hostilities. Anonymity is a safe and fine fortress from which to level ill-timed, ill-judged, and unbalanced attacks against professional colleagues.

It is well for all of us to remember that, as doctors, we must both *minister* and *administer*. The time to discuss the relative importance of these two professional functions, as well as to what extent they can be, have been, and are being combined, is not now, when all our energy is required to serve, in our professional capacity, our air-crews and the ground-staff by whose efforts our aircraft are maintained.—I am, etc.,

FREDERICK W. ROQUES, Group Capt., R.A.F.
Another Temporary Medical Officer.

SIR,—Of course "Temporary Serving Officer" is right when he affirms that Air Cdr. Cade and Conybeare are making a serious mistake when they paint an idealistic picture of Service medicine. Probably if he and I were in the same consultative position we should be in a different position clinically to make similar assertions.

I speak as a resident medical officer of a teaching hospital before the war, and over seven years as a reserve officer in one of the Forces. I fully endorse your correspondent's views, and agree with him when he says that the vast majority of Service doctors, while recognizing the need for compulsory regimentation in time of war, deplore the system and accept with resignation the methods of the bureaucratic machine. If I were a sole example of a medical officer bereft of clinical work for five years I should not grumble but accept the position as inevitable. But the "anomalies and abuses" do exist; administrative posts do carry promotion, which more often than not is not indicative of merit but dependent on the recommendation of the commanding officer, who may know little or nothing of the individual professional capabilities, and regards him as a "good chap." I could quote scores of cases where competent men are not getting clinical work because the

key posts are for the most part held by regular officers. The medical officer is not assessed on clinical merit: I know of an expert in tropical diseases who functions as a medical transport officer abroad. A large part of medical organization could be fulfilled by non-professional officers performing the house governor's duties of a civilian hospital.

How many patients in Service hospitals seek the advice of their own family doctor privately while on sick leave or when the opportunity presents itself? There are many illnesses of mind and body which the patient prefers not to include in a Service record compulsorily reported by the Service medical officer.

Do let us think more of the art of medicine—of clinical work first and foremost—the best possible treatment for all and sundry by every available means; but doctors and not administrators must work out the best means how.—I am, etc.,

"PERMANENT RESERVE."

Psychological Medicine and the Family Doctor

SIR,—I think it only fair that a senior family doctor be allowed some observations on Dr. Gillespie's article (Aug. 26, p. 263).

The whole article suggests that the family doctor does not realize the psychological basis of his patients' complaints. This is not true. Dr. Gillespie states: (1) Dr. Halliday found 35% of his chronics to be entirely psychological. (2) Clouston found 50% of his immediate neighbours aberrated. (3) Two people in un congenial jobs developed the one vertigo and the other headaches. (4) A man in the Army developed a skin disease because to please his father he volunteered for dangerous jobs he had no intention of pursuing further.

In answer I would say: (1) Halliday's material consisted of a fraction of the family doctor's work. How many did he cure? (2) Clouston was the only constant factor among those demented variants. Could it not be that Clouston was abnormal? (3) The only cure for those two people would be to change their jobs to suit them and to promote the stick-in-the-mud. As society is constituted one cannot do this. The only effect would be to have all the rest of their mates becoming vertiginous and "headachy" as the shortest road to a change of job and promotion. (4) Similarly the cure for this man is to give him suitable environment and please his father at the same time. How can you run an Army on such a footing?

Assuming that the psychologists are correct, is it right treatment to mass the ordinary sick in hospitals and the mentally sick in mental hospitals? The psychological pattern of the average hospital ward would puzzle a psychiatric Solomon. How terrible that little children when sick should be massed together in order that their complexes may be fixed for life!

The family doctor gets tired of the specialists talking down to him. It would be laughable were it not that the general public more and more are reading those medical articles and the sensational press delights to exploit them. How it loves to cull from the oratory of the specialist the shortcomings of the family doctor!—I am, etc.,

Glasgow.

JAMES COOK.

Prevention of Industrial Dermatitis

SIR,—In his further letter on this subject (Aug. 26, p. 290) Dr. L. B. Bourne misquotes the incidence figures for industrial dermatitis in 1943, as set out in my report (May 13, p. 660), by adding the machine-shop totals to those of the factory as a whole, in which of course they were included. He claims only "two cases in many thousands of workers this year," but I note that in his former letter (July 8, p. 57) he gave "two notified cases during the past year," and he then admitted also "a number of rashes of various types due to sensitization from industrial products." He does not give the total incidence of all industrial dermatoses in his factory and those losing any time, as I have done, and without which no comparisons can be made. Two notified cases—that is, cases absent from work over 3 days—may mean a large case incidence, and even skin diseases that are cured at the factory surgery without absenteeism cause a great deal of lost working time in attendance for treatment. Dr. Bourne infers that I rely solely on skin cleansing by means of the neutral sulphonated

castor oil (N.S.C.O. cleanser), and ignores the stress I laid upon the Factory Department's recommendations as to machine guarding, protective clothing, and adequate supervision. I would remind him also that my success with the N.S.C.O. cleanser followed my previous failure to prevent the occurrence of oil and paraffin dermatitis with barrier creams before, and lotions after, work. My statistics for all industrial dermatoses to date are as follows:

	1942	1943	1944 (7 months)
Case incidence	414	185	7
Ratio to personnel	12.5%	5.7%	0.03%
Notifiable cases	6	2	2

The N.S.C.O. cleanser was first used in Nov., 1942, and its use was gradually extended to workers on all "dirty jobs" throughout our factories. My own experience with it is being confirmed by the experiences of 54 other large industrial concerns and Royal Ordnance factories to which it has been supplied. Even if barrier creams, in machine shops, would do all Dr. Bourne claims, I greatly prefer the simplicity of the N.S.C.O. cleanser to the application and removal of the barrier substance. The N.S.C.O. is obtainable from Reynolds and Branson Ltd., 13, Briggate, Leeds, 1.—I am, etc.,

N. HOWARD MUMMERY.
Medical Officer, Aircraft Factory.

Thumb-sucking

SIR,—Dr. Mary Sheridan, writing of certain speech defects and malocclusion of the jaws (Aug. 26, p. 272), says: "The frequency with which I either observed thumb-sucking myself or obtained a history of the habit from the mothers leaves no doubt in my mind of the permanently harmful effects of this practice." Is her mind not shedding its doubt on this subject much too easily? Did she contrast the percentage of thumb-suckers among her maloccluded cases against the percentage found in normal controls, or is she merely mistaking her clinical impression for scientific observation?

My own clinical impression, although gained from a much smaller number of children, is precisely the reverse of hers—namely, that thumb-sucking is not important so far as dental occlusion is concerned. I have noticed, too, that it is the flesh-motifiers who inveigh most heavily against the habit. If any scientific observations on thumb-sucking have ever been made the references would be of interest. If there are none we ought not to make any further oracular statements about it.—I am, etc.,

COLIN EDWARDS.

Débridement

SIR,—In your leading article on the control of gas gangrene in your issue dated May 20, 1944, I was surprised to find the word "débridement" misused by the writer when he meant to say "excision." Reference to a dictionary or a work by a French surgeon will show that "débridement" means the opening up of a wound and all its recesses to facilitate the removal of foreign bodies and the establishment of drainage. A leader-writer's use of words should be above reproach.—I am, etc.,

India.

R. F. W. K. ALLEN.

Dental Caries

SIR,—Dental caries is not a rare disease; most of us, although we are not dentists, have had an intimate acquaintance with it. We are familiar with the whitened sepulchre which shows only a slight stain although caries has penetrated to the pulp tissue. It is highly probable that cases of this type were missed by Mellanby and Coumoulos in their survey of London school-children (*B.M.J.*, 1943, 1, 837). But to explain the increase of the "non-caries" group that they found it would be necessary to assume that the percentage of children who had caries of this type and no obvious caries had increased by 17.7 between 1929 and 1943. Would not this be much more improbable than an actual reduction in the incidence of caries? It should be possible to get statistics that would answer this question. Without some statistics to support it the objection raised by Miss Smith (*B.M.J.*, 1944, 2, 94) does not seem valid.—I am, etc.,

London, E.1.

J. R. MARRACK.

Obituary

SIR JOHN LUMSDEN, K.B.E., M.D.

Sir John Lumsden, whose death is announced from Dublin, had done extremely valuable work for the Red Cross in Ireland before, during, and after the last war. In 1915 he was made a Knight of Justice of the Order of St. John of Jerusalem, and in 1918 he was created K.B.E. In more recent years he held office as chairman of the Joint Committee in Eire of the British Red Cross Society and the Order of St. John of Jerusalem.

He was born on Nov. 14, 1869, at Drogheda, son of John Lumsden, a bank manager, and received his early education at the Dublin High School and at Taunton School. At Dublin University he graduated B.A. in 1891, M.B., Ch.B., B.A.O. in 1894, and proceeded M.D. in the following year. Soon afterwards he was appointed medical officer to Guinness's brewery in Dublin, and began to organize the medical service for the workmen of that great business and their families. In 1903 he formed the first Division of the St. John Ambulance Brigade in the South of Ireland, and in 1914 was in command of a large company of trained ambulance workers, of whom 70 had reported for duty with the Royal Naval Sick Berth Reserve by Aug. 6 of that year. From the outbreak of the last war he was the driving force behind the organization of war hospitals and nursing services in Southern Ireland, using his own house in Fitzwilliam Place as a depot and distributing centre. Lumsden and the ambulance teams under his leadership tended the wounded in the streets under fire during the Easter week rebellion in Dublin in 1916, regardless of their personal safety. His outstanding courage was recognized by the award of the silver life-saving medal of the Order of St. John and of the British Red Cross Society's medal for special services. During the last two years of the war he served in France with the rank of temporary major, R.A.M.C., on the staff of No. 83 General Hospital, B.E.F.

In addition to his work as chief medical officer to the firm of Arthur Guinness and Co. Sir John Lumsden was for some years senior visiting physician and lecturer on clinical medicine at Mercer's Hospital, Dublin; consulting physician to the Royal National Hospital for Consumption, Newcastle; and external examiner in medicine for the National University of Ireland. He had also been consulting medical adviser to the Commissioners of Irish Lights, and, for a year, physician to the Household of the Lord Lieutenant of Ireland. He was a Deputy Lieutenant of the City of Dublin and a Governor of the Rotunda Hospital, whose licence in midwifery he had obtained in 1893. He was the author of two small books, *Hints on Infant Feeding* (1900) and *Dietary Studies in Dublin* (1904), and contributed a number of papers on professional subjects to this and other medical journals. He joined the B.M.A. fifty years ago.

We regret to announce the death at Sevenoaks on Aug. 25 of Dr. JOSEPH LANGTON HEWER at the age of 84. He had been surgeon to the Mildmay Cottage Hospital, temporary assistant physician to Queen's Hospital for Children, Hackney, and honorary medical officer to the Invalid Children's Convalescent Home, Winifred House, Tollington Park, and the Home for Confirmed Invalids at Highbury. He came of a medical family, being the son of J. H. Hewer, M.R.C.S., who practised for many years at Highbury, in North London, and had several brothers who were members of our profession. J. L. Hewer was educated at University College School and St. Bartholomew's Hospital, and graduated M.B., B.S.Lond. (with honours) in 1883, took the F.R.C.S. in 1884, and the M.D. in 1886. He was in partnership with his father until the latter's death in 1893, when he moved into the old house and continued to practise until 1913, when he retired and moved to St. Albans. On the outbreak of the last war he helped some of the overworked local practitioners, and at its conclusion returned to London, where he had a consulting room with the late Dr. John Adams in Aldersgate Street. Retiring for the second time he made his home at Sevenoaks. Dr. Hewer will be remembered not only for his professional skill but as a humble and earnest Christian. He leaves a son, Dr. C. Langton Hewer, the well-known anaesthetist, and two daughters.

Dr. NATHAN GRAHAM WIGRAM, F.R.C.S., of Sloane Street, S.W., died on Aug. 30. Dr. A. Piney writes: The sorrow caused by the deaths of friends is often increased by the impersonal manner of the writers of obituary notices. One might suppose that the advice of Mephistopheles to the student had been taken seriously: "Wer will was lebendig's erkennen und beschreiben, Sucht erst den Geist heraus zu treiben." This thought comes to me at the loss of "Nat" Wigram, who was not only a first-class doctor but also a man of amazingly vivid personality. His far-sighted and comprehensive knowledge of his patients made him their trusted friend as well as their medical adviser—an adviser with whom they rarely argued, so certain were they of his integrity and professional skill. And those consultants to whom he referred his patients knew Nat as a man capable of reasoned criticisms of their opinions; and not only was he capable of doing so, he did so when he thought necessary in a way that nobody could ignore. He expressed himself forcefully and clearly, but nobody took it ill, because it was always obvious that the patient came first and the consultant's feelings a long way after. Wigram was a man to whom life was well worth living; and, although he had known for some years that his illness must prove fatal, he never let his own troubles make any difference to the care he gave his patients or to his intense interest in the progress of medicine. When he was confined to bed by the relapse that proved fatal, as he knew it would, he often said, "At least I have always given my patients good service." Death had no terrors for him, for, as he said more than once, "I have done most of the things I wanted to do, and, on the whole, have not done them badly." Those who knew Wigram will agree that he spoke no more than the truth. Well could he have said, "I warmed both hands at the fire of Life; it sinks and I am ready to depart." Wigram's death would have been a great loss at any time, but, in these days of standardized thinking, the passing of one who respected the opinion of the expert, while still using the perspicacity of the really good general practitioner, leaves a gap in the medical and social life of London.

We regret to announce the sudden death on Sept. 2, at Saltburn-by-the-Sea, Yorkshire, of Dr. ERNEST JOSEPH BURNETT in his 80th year. He studied medicine at Edinburgh University, graduating M.B., C.M. in 1887, and he obtained the M.R.C.P.Ed. in 1898. He was for many years consultant to the Brine Baths at Saltburn and medical officer to the Northern Convalescent Home there; he had also been surgeon to the North-Eastern Railway, medical officer to the Soldiers' Convalescent Home at Skelton, and medical examiner for the Women Emigrants Society and for the Canadian and Australian authorities responsible for immigration. Dr. Burnett joined the B.M.A. in 1899 and was a past-president of the North of England Branch. He was for a considerable time a Justice of the Peace, and received the M.B.E. in 1920.

Dr. GEORGE BARTLEY MCKEAN died suddenly at his home in Ledbury, Herefordshire, on Sept. 2. He was born in Belfast in 1876 the son of William McKean, and after schooldays at the Royal Academic Institution, Belfast, came to London to study medicine at University College Hospital. He qualified M.R.C.S., L.R.C.P. in 1902, and took the M.B., B.S.Lond. degrees and the F.R.C.S.Ed. diploma in 1906. From 1908 until his retirement from active work in 1941 he was honorary surgeon to the Ledbury Cottage Hospital and held a number of other local appointments. Before settling in Herefordshire he had been senior obstetric assistant at U.C.H. and senior assistant medical superintendent of St. Pancras Infirmary, Highgate. Dr. McKean joined the B.M.A. in 1911 and was chairman of the Herefordshire Division in 1924-5.

Dr. EDWARD PHILLIPS, late of Coventry, died peacefully at Oxford on Sept. 4 at the age of 86. After studying medicine at Queen's College, Birmingham, he took the L.R.C.P.Ed. diploma in 1881, the M.R.C.S.Eng. in 1885, and graduated M.B. of Durham University in 1886. After holding the post of senior resident medical officer at the Children's Hospital, Birmingham, Dr. Phillips practised in Coventry for half a century, and served for many years as honorary surgeon to the Coventry and Warwick Hospital and consulting surgeon to the Coventry Union Infirmary. He first joined the B.M.A. in 1882, and represented his Division at the Belfast Meeting of 1909. Apart from his medical record Dr. Phillips was a pioneer motorist, and several of his letters on the motoring requirements of medical practitioners were published in the earliest years of this century. He designed a motor cycle for use by medical men in 1899 and used it in his own practice; he also took part in the first 1,000-mile motor-car reliability trial held in this country. He leaves a widow and two sons, one a brigadier in the Army and the other serving in the R.N. emergency vessels.

No. 34

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Aug. 26.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included) (b) London (administrative county) (c) Scotland (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each of the two diseases, for: (a) The 126 great towns in England and Wales (including London) (b) London (administrative county) (c) The 16 principal towns in Scotland (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1944					1943 (Corresponding Week)

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes paratyphoid fever for England and Wales and Eire.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In England and Wales the notifications of measles were fewer by 492, and of whooping-cough by 287; dysentery notifications were up by 51.

The incidence of measles has now been falling for seven weeks. During this period the weekly notifications have dropped by 57%. This week Lancashire reported 95 fewer cases than last. The largest decline for whooping-cough was in Staffordshire, where there were 49 fewer cases.

Dysentery notifications again rose sharply, and the total, 299, has been exceeded only twice during the war. During the week the largest of the new outbreaks were in Buckinghamshire, Eton R.D. 15 and in Huntingdonshire, St. Neot's R.D. 20. The other large centres of infection were Leicestershire 36, Lancashire 28, Essex 28, Glamorganshire 21, Surrey 15, Nottinghamshire 14, Yorks West Riding 13, Cheshire 11, London 11.

Polio-myelitis—25 cases were recorded during the week, the largest total for two years. The cases occurred in twenty-three administrative areas.

In Scotland the notifications of dysentery were 20 higher than last week. The largest returns were Glasgow 42, Edinburgh 31, Ross and Cromarty County 12.

In Eire another increase of 37 in diarrhoea and enteritis was reported. 115 of the 161 cases were recorded in Dublin C.B.

Quarterly Return of the Registrar-General for Scotland

During the second quarter of this year the birth rate in Scotland was 20.5 per 1,000 and was 1.3 above the average for the five preceding June quarters. Infant mortality was 57 per 1,000 live births and was 10 below the five-years average. Maternal mortality was 3.6 per 1,000 live births, this rate being 0.5 below the average of the five preceding second quarters. The general rate was 12.2, being 1.1 below the five-years average and the lowest rate ever recorded for any second quarter. The death rate from tuberculosis was 79 per 100,000 for all forms and 57 for respiratory tuberculosis; these rates were 8 and 7 respectively below the five-years average. The death rate from the principal epidemic diseases, 16 per 100,000, was only half of the average rate for the five preceding second quarters. The deaths in this group included influenza 51, whooping-cough 49, diphtheria 45, cerebro-spinal fever 27, measles 21.

Week Ending September 2

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,137, whooping-cough 1,389, diphtheria 445, measles 1,069, acute pneumonia 297, cerebro-spinal fever 27, dysentery 419, paratyphoid 13, typhoid 10, polio-myelitis 25, polio-encephalitis 7.

Medical News

A Regional Conference on Population Problems, under the auspices of the British Social Hygiene Council, will be held at the Reardon Smith Lecture Theatre, National Museum of Wales, Cardiff, on Friday, Sept. 29. The object is to consider the more effective application of present scientific knowledge to this urgent social problem. Those attending will represent education, health, medicine, law, economics, social welfare, and the Services. The conference will be divided into two sessions, to be preceded at 10.45 a.m. by a civic welcome by the Lord Mayor of Cardiff. The hon. secretary of the local Conference Committee is Dr. J. Greenwood Wilson, F.R.C.P., Public Health Department, City Hall, Cardiff.

Twenty-six cases of blindness caused by flying bombs have already been notified to the National Institute for the Blind. They include 7 men, 13 women, 5 young people, and a child of 18 months. The baby is in one of the Institute's Sunshine Homes, and ten of the others are at its Homes of Recovery receiving special training for their changed conditions ahead. Some are still in hospital. Relatives of great casualties are urged to notify the National Institute, 224, Great Portland Street, W.1, as soon as the medical verdict is known. In the earliest days much can be done to restore the blinded person's confidence, and training can be begun during convalescence.

In view of the continuance of emergency conditions the Minister of Health has extended until March 31, 1946, the period during which complete arrangements under the Cancer Act, 1939, should be submitted by local authorities.

Dr. James Ferguson, M.O.H., Surrey County Council, has been elected chairman of the Council of the Royal Sanitary Institute, to take office on Oct. 1.

Lieut.-Gen. Sicé, who recently visited France, as a delegate for the Free French social services and representative of the French Red Cross Society, to investigate conditions in Normandy, Brittany, and Anjou, has reported that, while the inhabitants of the rural districts have not suffered too severely from war conditions, the plight of adults and children in towns and cities is serious. He found no sign of epidemics, but the general level of health was not good, especially in Normandy. Substantial medical supplies had been sent for the immediate use of children and sick persons, but one of the chief difficulties was that no great ports were available in France. Lorries loaded up in this country were taken on board ship and disembarked without unloading, so that they could drive straight away after landing. General Sicé paid a tribute to the British Red Cross organization for what it had already done, but added that milk, condensed milk, and fats or halibut and cod-liver oil were required for children who had long been almost completely deprived of fats, and also meat extracts for anaemic children. The child mortality was very much higher than in normal times, especially as a result of tuberculosis.

The use of dried milk in combating gastro-enteritis, which has become prevalent among young children in Glasgow, is advised by Sir Alexander Macgregor, M.O.H. for the city. Where liquid milk is given to babies, mothers are advised to boil it first.

The Services

Fl. Lieut. Alfred George Spencer, R.A.F.V.R., and Flying Officer Albert Arthur, R.A.F.V.R., have been awarded the George Medal. The citation in the *London Gazette* reads as follows:

One day in February, 1944, an aircraft, carrying a 500-lb. bomb and incendiaries, crashed near a Royal Air Force station and immediately caught fire. Flying Officer Arthur, a gunnery instructor, was soon on the scene, and despite the great heat and exploding ammunition, he attempted to rescue the crew. Shortly afterwards he was joined by Fl. Lieut. Spencer, the station medical officer. The wreckage was blazing from end to end, and several times these officers were compelled to break off their rescue attempts. Flying Officer Arthur entered the burning aircraft no less than four times, with a handkerchief tied round his nose and mouth. At the fourth attempt he was driven back by the heat and flames, his eyebrows being burnt off and his right trouser leg and pocket burnt. Fl. Lieut. Spencer stayed close at hand and searched in the wreckage for possible survivors. It was not until the bombs were red hot and Fl. Lieut. Spencer was certain that the crew must be dead from the heat that these officers abandoned their efforts. They then warned the fire party to withdraw and cleared the area of spectators just before the 500-lb. bomb exploded. Although the attempts of these officers to rescue the crew were in vain, they displayed high courage and a complete disregard of their own safety.

CASUALTIES IN THE MEDICAL SERVICES

Capt. EDWARD NEIL WHITLEY, R.A.M.C., who was wounded in Normandy in June and died at a hospital in England on Aug. 29, aged 26, studied for the medical profession at Cambridge and at the London Hospital, qualifying M.R.C.S., L.R.C.P. in 1942; in November of that year he joined the R.A.M.C. as a temporary lieutenant, after serving as receiving-room officer at the London Hospital.

Killed in action in Normandy while attending wounded.—Capt. R. J. D. Carrick, R.A.M.C.

Died of wounds.—War Subs. Lieut. T. Notman, R.A.M.C.

Wounded.—Temp. Col. R. D. Cameron, M.C.; Temp. Lieut.-Col. G. C. Dansey-Browning; Temp. Major M. F. X. Slattery; Capt. W. J. Morrissey; War Subs. Capt. W. N. Calder, W. F. Caldwell, S. Conlan, J. Cowan, T. S. Jones, T. S. Maw, W. H. P. Minto, J. Morrison, J. G. Mott, G. M. Sinclair, and A. Young; Lieuts. 1 G. D. Bell and W. G. Harding, R.A.M.C.

Universities and Colleges

UNIVERSITY OF EDINBURGH

The Nutfield Provincial Hospitals Trust, on the recommendation of its Scottish Advisory Committee, has made a grant in aid of further research in neonatal and infant problems, to be carried out by the Department of Child Life and Health of Edinburgh University at the Simpson Maternity Pavilion. The research will be directed by Prof. Charles McNeil and the experiment will be under the auspices of the University and the Royal Infirmary of Edinburgh.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

At a meeting of the Faculty held on Sept. 4, the President, Dr. James H. MacDonald, in the chair, the following was admitted a Fellow of Faculty *qua* Physician: R. Y. Keers, M.D. R. Mailer, M.D., F.R.C.S.Ed., was admitted a Fellow of Faculty *qua* Surgeon.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London*. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London*.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent, London*.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Sensitivity to Sulphonamides

Q.—Is there any way of desensitizing a patient who is hypersensitive to sulphathiazole? One gramme of the drug causes irritation of the hands, round the edges of the lips, and round the anal margin, with the formation of an urticarial rash on the dorsum of the hands. Sulphapyridine causes a similar reaction.

A.—It is not really possible to give a safe answer to this question as experience has been so limited. The available literature was reviewed in the *Lancet*, 1944, 1, 406, and the *Journal*, 1944, 2, 248. It is shown that desensitization to the sulphonamides has been brought about by oral administration of the drug to which the patient is sensitive, beginning treatment with a small amount—e.g., 0.1 g. b.d.—and rapidly stepping up the dose—e.g., to 1.0 g. five times a day on the 8th and 9th days. The procedure seems hazardous in view of the risk of exfoliative dermatitis and other complications. Desensitization might more safely be begun by the injection of blood serum from a donor who has been taking sulphathiazole for five days. Such serum contains an antigen which causes an allergic type of response after intradermal injection in sensitive individuals. The initial dose would be 0.05 c.cm. It is not known whether this technique has actually been put into practice. Neither of these procedures can be strongly recommended now that penicillin is becoming available and sulphonamides are presumably no longer indispensable. Nothing is to be gained by trying other sulphonamides as the patient is almost certainly sensitive to the sulphanilic acid radicle, which is common to the whole group.

Tubercle Bacilli in Junket

Q.—A patient tells me it is a well-known fact that in the process of making junket any tubercle bacilli in the milk will be destroyed, but I can find no reference to this in the literature. I should like authoritative information on the subject.

A.—We know of no evidence to support this statement. Observations on Cheddar cheese made from infected raw milk have shown that tubercle bacilli may survive for several weeks. In cheesemaking, in which both an acid-producing "starter" and rennet are used, the acidity reached is considerably higher than in the preparation of junket, in which rennet alone is used. If it is assumed that the acid is mainly responsible for the gradual destruction of tubercle bacilli in cheese—at any rate in the early stages of ripening—it is difficult to understand why junket should prove more active in this respect than cheese. This statement might be classed with other "well-known facts," such as that junket cannot be made from pasteurized milk, which are known to be cherished fallacies.

Ingrowing Toenail

Q.—What is the best palliative treatment for ingrowing toenail? When should one decide that removal of the nail is necessary?

A.—There are several palliative methods of treatment for ingrowing toenail which are adopted in home treatment. The best-known are cutting a V-shaped wedge from the free edge of the nail as far back as possible towards its root (rather hard on the socks), scraping or filing the centre of the nail so that it can arch upwards and thus relieve some of the pressure on the lateral grooves, or applying a small piece of thin metal foil under the lateral nail edge and bringing it out over the rolled-over fold of skin. A most important point is to determine whether there is a spicule (splinter) of nail growing forwards in the lateral groove due to the difficulty of cutting the nail right out to its hidden lateral margin. This spicule must always be removed, for it is a common cause of pain and produces a portal of entry for infection. None of these measures is more than palliative. If the nail causes repeated trouble and disability there should be no hesitation in advising radical surgical

treatment. Removal of the nail is unsatisfactory, even when the nail bed is included; the most certain treatment is partial amputation of the terminal phalanx, including of course the whole of the nail bed, by a long plantar flap. This leaves a slightly shortened nail-less toe which heals rapidly and results in no disability whatsoever.

Male Climacteric

Q.—A professional man of 50 years for the past months has had very little sexual desire, and penile erection has been difficult to attain and lasts for a very short time. Intercourse has gradually diminished in time till now it lasts only seconds. Is this a case of "male menopause"? If so, what hormone therapy will restore the sexual powers?

A.—This may be a case of male climacteric, although the age is somewhat early. (The term "menopause" means cessation of menstruation, and should not be used, therefore, in the case of the male.) If the diagnosis is correct 25 mg. of testosterone daily, intramuscularly, should produce improvement within two weeks; then treatment could be continued with methyl testosterone, 5 to 10 mg. three times a day, allowed to dissolve under the tongue, or by implantation of 600 mg. of testosterone in the subcutaneous fat. Should there be a complete absence of response, the question of psychological impotence should be considered.

Arum maculatum

Q.—A child recently was believed to have swallowed the seeds of *Arum maculatum* (cuckoo-pint, lords-and-ladies). In three elementary books these seeds are described variously as dangerously poisonous, poisonous, and medicinal. I should be obliged if you would kindly say whether these seeds are in any way harmful.

A.—All parts of the plant of the *Arum maculatum* are poisonous. The reason why different books describe this plant as "dangerously poisonous," "poisonous," and "medicinal" may be due to the fact that most substances which are medicinal in small doses may become poisonous or dangerously poisonous in greater doses. The root particularly contains an acrid juice which acts as a powerful irritant, and although it has been used medicinally as a diuretic and stimulant, and occasionally as a purgative, its use has now been discontinued. The seeds are less poisonous than the tubers, but it may be quite definitely stated that they are poisonous.

Rorschach Test

Q.—Where can I obtain the materials necessary to carry out the Rorschach test for temperamental traits? Can the interpretation of the test be self-taught? Which books should be read?

A.—The Rorschach test cards have been on sale at Messrs. H. K. Lewis, Gower Street, London, W.C.1, but are in short supply. The interpretation can be self-taught, but only at the expense of great time, trouble, difficulty, and mistakes. The Rorschach Institute in the U.S.A. demands a 3-year period of training! Read Rorschach's original work, of course—i.e., Hermann Rorschach, *Psychodiagnostik*, translated into English by Lémkau and Kronenberg, Verlag Hans Huber, Berne, Switzerland (distributed in the U.S.A. by Grune and Stratton, New York); also Samuel J. Beck, *Rorschach's Test*, Vol. I, *Basic Processes*, Grune and Stratton, New York. And a simpler manual for the beginner is Klopfer and Kelly, *The Rorschach Technique*, Harapp.

Seasickness

Q.—Is there any effective treatment for seasickness? The problem arises in respect of an apprentice to the Trinity House Service. He is very keen to remain at sea, but in bad weather is frequently too ill to perform his duties, and he fears he will be invalided from the service.

A.—A large number of remedies have been proposed for seasickness. Physiotherapeutic measures probably act mainly by suggestion and do not seem to be effective. Drugs with most reputation are those which depress the parasympathetic nervous system—e.g., atropine, hyoscine; those which stimulate the sympathetic nervous system—e.g., amphetamine or benzedrine, and methedrine; and those which depress the central nervous system—e.g., chlorbutol and barbiturates. Careful studies carried out on sea-borne troops in this war suggest that hyoscine in doses of 1/100 gr. is the only remedy which will significantly reduce seasickness and at the same time will not impair efficiency. These results, however, apply only to short voyages, and it is doubtful whether hyoscine can be expected to inhibit seasickness over a period of days. Many famous sailors, including Lord Nelson, were sick whenever they returned to sea again. In such cases acclimatization occurs in about three days and persists so long as the sailor is in the same type of ship. Acclimatization wears off after about three weeks on shore. In a few instances acclimatization never occurs and the subject is always unhappy in rough weather. The tendency nowadays is to think that in these men the mind is divided against itself and the superficial

keenness really hides a latent or unconscious distaste for the sea. Certainly no physical or pharmacological remedy is likely to prove effective, and the victim would be well advised to take up another profession while he is still young.

Girl with Large Breasts

Q.—An active girl aged 18, of normal height and weighing 12 stone, is unhappy about the largeness of her breasts. She is very sociable, but the size of her breasts makes it difficult for her to "look well-dressed" and makes her feel self-conscious when she is playing tennis. She is in excellent health, with no menstrual troubles. She is not worried because she is stout, but because her bust is so large. What is the best treatment?

A.—While oestrogens do develop inadequate breast tissue, it is much more difficult to reduce excessive breast tissue or adiposity which is localized in the breast region. Testosterone in large doses might reduce breast tissue, but only by suppressing ovarian activity and producing some degree of hirsutism, the end-result being worse than the initial stage. Diet and thyroid combined with mercurial diuretics might reduce the general adiposity, and incidentally the adiposity in the breast region, but it is questionable whether these are worth while in view of the excellent general health. Plastic surgery sometimes produces excellent results, but not invariably so, and should not be lightly undertaken. On the whole it would appear that a philosophical and psychological approach, which would permit the patient to accommodate herself to her build, is the best course.

Tetanus Prophylaxis

Q.—What modifications has the experience of war brought to tetanus prophylaxis, and what differences still exist between the English and American methods? What course of prophylaxis would you suggest for an agricultural community, and how often should it be renewed? Should farm workers be immunized?

A.—The English fighting Forces and the American Army immunize soldiers on enlistment with tetanus toxoid; the American Navy uses alum-toxoid. Two or three injections spread over about six weeks are customary. The tendency is to repeat one or more of these doses periodically—e.g., at six- or twelve-monthly intervals and prior to battle service. Thus far there is no fundamental difference between the English and American methods (*Journal*, 1943, 2, 818). The main difference is in the treatment of the wounded soldier. The American practice has been to inject prophylactic toxoid (or alum-toxoid) into the patient, the aim being to elicit a rapid rise in the man's own self-produced active immunity that will outmatch the production of toxin in the wound. The English authorities believe that this rise may not occur rapidly enough, so they inject antitoxic horse serum, so-called "antitoxin," which gives immediate passive immunity. Probably almost all English immunologists are convinced on the evidence that the English plan is sound, and some American writers favour it.

Among agricultural workers the risk is small; tetanus rarely occurs. The tetanus bacillus requires special conditions for its dire work. A deep war wound with much necrosed tissue or damaged muscle deprived of proper blood supply through arterial damage—plenty of nutrient for the bacillus with little or no oxygen present—provides ideal conditions. So, too, would a compound fracture of the leg of a farm worker crushed by a wagon-wheel in a dung-soiled yard or field. But such lesions are rare in farm practice. Two courses are open to the doctor. (a) If he is cautious and leans strongly towards insurance, he will inject all farm workers with two doses of toxoid separated by six weeks. He can increase the insurance against risk by giving, as in the Army, a reinforcing dose every twelve months. He will thus confer a high protection. In France in 1940 and after Dunkirk eight cases occurred, all in unimmunized men, and later experience in the Middle East and in the American Forces (see *Amer. J. publ. Hlth.*, 1944, 34, 29) fully bore this out. If his farm worker is injured the doctor will also give a dose of tetanus antitoxin—e.g., 3,000 units. (b) Probably the average practitioner will compromise and, in view of the smallness of the risk, will not urge active immunization on his patients. He will always have at hand tetanus antitoxin—modern enzyme-treated or refined, little liable to cause reaction—and will give at least 3,000 units intramuscularly when he meets with a compound fracture of the kind instanced or a deep puncture with the prong of a dung-soiled fork, or even any wound that is not superficial (*Journal*, 1943, 2, 818).

B. coli Bacilluria

Q.—Is it safe to continue mandelic acid therapy for a bacilluria (heavy infection, *B. coli*) over a long period? At what period would it be considered useless to continue?

A.—It should first be pointed out that during mandelic acid treatment the pH of the urine should be watched, and reduced to 5.0, if necessary, by the administration of ammonium chloride in addition. If this has not been done it may be the reason for the failure of the treatment. A fortnight should be regarded as the

longest period for which it is likely to be useful to continue such treatment: it should usually achieve its effect in a week. The dangers of this treatment are acidosis and renal damage. Acidosis is not likely to be produced if renal function is good, but hyperpnoea should be watched for, and the alkali reserve estimated should it occur. Some degree of renal damage, if only temporary, is indicated by the presence of large numbers of casts in the urine, and this finding contraindicates long continuance. If the infection is, as stated, due to *B. coli* alone, and unaccompanied by any other lesion of the urinary tract, it should also respond to sulphanilamide.

Cumulative Effects of Phenobarbitone

Q.—In a reply to a question on the treatment of whooping-cough (Aug. 12, p. 230) you advise phenobarbitone gr. 1/4 b.d. for a child of 1 year, provided cumulative effects are watched for. What are the cumulative effects? I have given it to adults for years and never seen any. Secondly, what dose would you consider safe for a child aged 1½ years, and for one aged 2 years, who are suffering from insomnia? They are active, intelligent children, quite healthy, and in London. They sleep in surface shelters, and keep both the mothers and others awake, to the distress of the mothers. The ordinary bromide and chloral mixtures—e.g., N.W.F.—have been useless, and I have been afraid to push the phenobarbitone further than 1/4 gr., as my experience with this drug in infants is limited.

A.—Cumulative effects of phenobarbitone are dizziness, lethargy, weakness, and inability to concentrate. In addition symptoms of idiosyncrasy are more prone to arise if the drug be given over a period of weeks. These are fever, itching, erythematous rashes, nausea, vertigo, diplopia, ataxia, and slurred speech. I should not use phenobarbitone as a hypnotic in young children. Its action as a hypnotic is relatively feeble. For the children in question 10 gr. bromide and 5 to 7 gr. chloral should succeed.

A Case for Investigation

Q.—A woman aged 59, since x-ray treatment of hyperthyroidism 4 years ago, has complained of severe paroxysms of headache and abdominal "spasms." The heart beats violently in the attacks. The noises in the head, and headaches, compel her to hold her head. She is incapacitated by the illness. She sleeps very little. No collapse after the attack (cf. adrenergic sympathetic). Functions normal except severe constipation. On examination she is well covered, is garrulous, and has patchy hyperaemia on chest. Pulse 108; B.P. 170/100. No tremors; no sweating. Routine urine examination normal. Amino-acids nil. Blood sugar 68 (repeated). I should particularly like to know whether the symptoms could be attributed to the hypoglycaemia, and whether this has been known to follow x-ray treatment of hyperthyroidism. There is no anaemia and no evident hypothyroidism. Vitamins in urine have been estimated, and this will be repeated after test dosage.

A.—It is not clear why elaborate vitamin studies should have been made in a case of this kind. The first question is whether the patient is suffering from hyperthyroidism, which might well account for her present symptoms; for this purpose the basal metabolic rate and the serum cholesterol are the relevant tests. Parathyroid tetany is unlikely to be present, but this possibility could be excluded by examination of the serum calcium. Hypoglycaemia is not known to follow x-ray treatment of hyperthyroidism. In any event hypoglycaemic attacks should not be diagnosed unless (1) the fasting blood sugar is below 60 mg. per 100 c.cm.; (2) the blood sugar is below 50 mg. per 100 c.cm. in an attack, and (3) the symptoms are relieved dramatically by the administration of glucose. Other possibilities in this case are psychoneurosis, Ménière's syndrome, migraine, and paroxysmal hypertension; in fact the range is too wide to give help without seeing the patient. As she has been ailing for some years it would seem wise to get a second opinion from a medical consultant who can view biological data and vitamins in their proper perspective.

Falling Hair

Q.—A married woman of 38 has been going grey for the past 6 years and the hair is continually falling out. There is no excessive seborrhoea, although the scalp is dry. She is perfectly healthy except that her periods are irregular and scanty. Can you suggest a remedy for this condition?

A.—Loss of hair may be attributed to both general and local causes. Thus the sudden loss of hair after fevers and the less abrupt thinning accompanying debilitating conditions are well known. Changes in the hair in certain hormonal diseases represent a part of the symptom-complex, as in myxoedema, where the phenomenon may render a patient almost unrecognizable. Men tend to become bald, women do not—a sex distinction which may be relied upon, with, of course, certain exceptions, to base a reassuring prognosis in women where the hair is falling out and where there is fear, without reason, of the onset of complete baldness. If seborrhoea is present, even if only represented by dryness or a

little dandruff, the outlook is favourable, and with treatment considerable improvement may be expected. Pomades and lotions are not favoured because of their messy nature, but this disadvantage can be avoided by applying a *small quantity* of an ointment containing 6% sulphur and 3% salicylic acid, a soft base to the ointment—i.e., arachis oil and vaseline. This is well rubbed into the scalp one night in the week and washed out the next morning, simple procedure easily carried out provided only a small quantity of the pomade has been used and well rubbed into the scalp. Resorcin lotion applied every morning enhances the result, but this is unsuitable for light or grey hair as it stains a yellow-brown. The application of ultra-violet radiation, or high frequency, the hair dresser's "violet-ray," is no better than a thorough brushing. Women's hair was more healthy and profuse before the change of fashion shortened it, because the prolonged nightly brushing of attention improved and maintained its condition. It is well, however, always to inform the patient that hair coming out following the application of a pomade or a shampoo is to be disregarded, as it is only the loose hair which has been cast.

LETTERS, NOTES, ETC.

Yeast in Furunculosis

Dr. M. A. COOKE (Bradford) writes: I was interested to read the letter of Dr. Watson Smith concerning the use of yeast in furunculosis (Aug. 19, p. 256). There is little doubt of its usefulness in certain cases of furunculosis and other skin lesions. Its action has been variously ascribed to its fermentative properties, to its vitamin B content, and also to its nuclein fraction. Supporters of the latter theory claim that yeast is as active therapeutically after it has been heated to 130° C. for about an hour. Concerning the local action of yeast, this has for some time been used in "face-packs"; not, however, with very marked results. This latter fact may be a result of the comparatively inert form of the yeast. I certainly agree with Dr. Watson Smith that brewers' wort is the most therapeutically active form; patients who have taken it not only appear to recover more quickly, but also testify to feeling brighter. It is, of course, difficult to exclude the psychological factor in view of the difficulty of arranging suitable controls. It is possible that it would be more efficacious if applied locally in the actively fermenting form. With reference to the analogy to penicillin, Gram-stained preparations of yeast almost invariably show staphylococci in addition to the various yeasts and fungi always present. This, however, would not exclude the fact that yeast may contain a fraction lethal to these and other organisms under certain conditions of purity and acidity. Certainly, as Dr. Watson Smith states, the pharmacological action of yeast offers many riddles to solve.

Wasp and Bee Stings

Dr. H. S. RUSSELL writes: The answer to the question about relief of pain (Aug. 26, p. 295) omits reference to the most effective method—1 c.cm. intradermal wheal of novocain adjacent to and including the sting. Relief is complete, immediate, and lasting.

? Case of Alkaptonuria

"GAMMA" writes: I was interested in the "Any Questions?" answer about a vaginal discharge (Aug. 26, p. 296). Would it be possible for the inquirer to test the urine for homogentisic acid, as it sounds like a case of alkaptonuria which has not been diagnosed hitherto? If this is the case, it is not the discharge which is stained the underclothes but the urine, which after the birth of the child tends to leak away more than it did and so now attracts attention.

"Vitamin B Deficiency in Allergic Patients": Correction

Dr. ARTHUR F. COCA, Medical Director, Lederle Laboratories, New York, writes: Referring to my previous communication [Jul. 22, p. 128] concerning the article by Drs. McSorley and Davidson I have to apologize for overlooking the fact that they were referring to the anti-anaemic liver extract, not the preparation of vitamin B complex.

Correction

In our column of Medical News (Aug. 26, p. 294) Miss Florene Horsburgh, M.P., was reported as stating that more than 300,000 beds in maternity homes have been provided during the war. The figure should of course have been 3,000.

T. J. Smith and Nephew Ltd., Neptune Street, Hull, have issued a pamphlet *Plaster of Paris in the Treatment of Burns*. This, they state, has been compiled with the help of surgeons with experience of war and civilian casualties, and it includes references to recent literature on treatment of burns. So far as restricted supplies allow a copy will be sent to any doctor on request.

INFLUENCE OF SYNTHETIC OESTROGENS UPON ADVANCED MALIGNANT DISEASE

BY

ALEXANDER HADDOW, M.D., D.Sc., Ph.D. JEAN M. WATKINSON, B.Sc., M.R.C.S., L.R.C.P.

AND

EDITH PATERSON, M.B., F.R.C.P.Ed.

WITH AN

ADDENDUM by P. C. KOLLER, D.Sc., Ph.D.

(From the Royal Cancer Hospital (Free) Fulham Road London and the Christie Hospital and Holt Radium Institute Withington Manchester)

In an investigation of the mechanism of action of tumour-producing compounds it was found that many carcinogenic hydrocarbons possess the property of retarding the growth of tissues, both normal and malignant (Haddow, 1935, for later references see Badger, Elson, Haddow, Hewett, and Robinson, 1942). In these compounds the correlation between carcinogenicity and growth inhibitory activity assumes considerable statistical significance, and it was further suggested that it is of aetiological importance as well tumour production by these substances being envisaged as a cellular adaptation to a protracted period of growth repression. In subsequent work to elucidate the molecular conditions determining inhibitory action, attention was paid to the synthetic oestrogens. It may be recalled that a few of the carcinogenic hydrocarbons themselves possess slight oestrogenic activity, while in certain cases these two classes show interesting relationships on chemical grounds. Thus the results obtained in animal experiments with a number of derivatives of the oestrogen triphenylethylene which may be likened, for instance, to a 9-phenylphenanthrene (with one ring disrupted) indicated that growth inhibitory activity may still be shown by compounds which depart from the polycyclic structure and possess only a resemblance in their carbon skeleton.

These findings may possibly be correlated with the fact that, on the contrary, certain of the oestrogens exert carcinogenic action in animals, although in a somewhat restricted sense and in experimental circumstances (of dosage, strain susceptibility, etc.) which are unlikely to be duplicated under the conditions of radiation in the human subject. The reviews of Gardner (1939) and Allen (1942) cite numerous instances of tumours occurring in experimental animals after long continued treatment with oestrogens examples being carcinoma of the cervix in mice, uterine fibromyomas in guinea pigs, mammary cancer, interstitial cell tumours of the testis in mice, pituitary adenomatosis in mice and rats, tumours of the suprarenal cortex in mice, oestrogenic transformations in mice, and various lymphoid and connective-tissue tumours including sarcoma. The induction of animal tumours by oestrogens is most readily elicited although by no means exclusively, in those tissues which are highly responsive to the physiological action of such compounds and the greatest number of reports deal with the reduction of mammary cancer in mice—e.g. by the synthetic oestrogens stilboestrol (Lacassagne 1938, Shimkin and Grady 1940) and triphenylethylene (Robson and Bonser 1938). Since the testis is markedly sensitive to oestrogen action which results in varying degrees of atrophy, the production of hypertrophy and tumours of the interstitial cells in the testes of mice

receiving oestrogens is of especial significance (e.g., Gardner, 1937, Hooker, Gardner and Pfeiffer, 1940, Bonser and Robson, 1940). There is, in short, a group of growth inhibitory substances which are clearly associated with the production of individual classes of tumour in laboratory animals under specially defined experimental conditions. The oestrogens thus provide a further example of the relation (only apparently paradoxical) that compounds possessing growth retarding properties in certain circumstances may also have either with the physiological stimulation of growth or with the induction of tumours.

The growth-retarding property of polycyclic aromatic compounds although under some experimental conditions more marked than that shown by the oestrogens, remains a subject for persistent investigation rather than clinical application. However it was judged reasonable to undertake the clinical trial of synthetic oestrogens in advanced human cancer which was beyond treatment by either surgery or radiation, with particular reference to tumours arising from such normal tissues as are most reactive to the physiological stimulus of these compounds—e.g., tumours of the breast or of the testis. Such an investigation is facilitated by the ready availability and low toxicity of the synthetic oestrogens.

The present paper reports the findings in 40 cases of carcinoma of the breast and in 33 cases of malignant disease in other organs, the majority of which were treated with triphenylchloroethylene, and the first of which (carcinoma of the bladder—see below) began treatment on Feb 18, 1941. Triphenylchloroethylene is of interest in two respects: first, because of its comparatively prolonged action (cf. Robson, Schonberg and Fahim, 1938), which seems to be related to its insolubility in body fluids, and, secondly, since Emmens (1941) showed it to be a true oestrogen—that is, one acting directly, or after chemical changes which can be effected locally, in contrast with the pro-oestrogens (including the parent hydrocarbon triphenylethylene) which require to pass into the general circulation before exhibiting oestrogenic properties. Apart from those cases treated with triphenylchloroethylene 7 were treated with the compound in which the chlorine atom is replaced by a methyl group (triphenylmethyl ethylene), and 14 with stilboestrol.

A. Triphenylchloroethylene

1. Late Malignant Disease of the Breast

Table I summarizes the data obtained in 22 cases. The drug was administered by mouth in all save Nos 21 and 22, which received it by the intramuscular injection of an aqueous dispersion.

It is clear that a proportion of cases showed a significant—although temporary—retardation of the growth of the tumour. Indeed, an initial regression of the lesions occurred in 10 of the 22 cases (Nos. 1, 2, 4, 6, 7, 12, 17, 18, 20, 21, Table I). In Case 1 a skin nodule remained stationary for a period of three months, during which the primary tumour was regressing. Again, secondary deposits in the lung developed in Case 18 during treatment, although the lesion in the breast showed

all of whom are now dead or have steadily advanced. It may be noted that the degree of retardation obtained was probably much less than could be expected from local irradiation.

In responsive cases the sequence of changes was characteristic, consisting of a purplish discoloration of the previously red, a flattening followed by disappearance of skin nodules, and the ulceration and disappearance of

TABLE I.—22 Cases of Late Malignant Disease of the Breast treated with Triphenylchloroethylene

Case	Age (yrs)	Previous History	Condition at Beginning of Treatment (No biopsy or section unless stated)	Treatment (Amounts in Grammes refer to Triphenylchloroethylene)	Result of Treatment (b.t. = Beginning of treatment)
1	71	Lump breast for 1 yr, ulcerated	Ulcer 12 × 9 cm replacing breast. Nodule over sternum. Enlarged lymph nodes both axillae.	10 g per week initial 252 g in 3 m. Interval of 2 m. Total 336 g. in 8 m.	Almost complete regression of tumour, then steady growth. No regression of axillary nodes. Died of lesions 16 m. after b.t.
2	33	Lump under arm 18 m. X-ray therapy. Recurrence 1 yr. later	Pregnant. Tumour in breast. Skin nodules, nodes involved.	21 g per week for 2 m. Interval of 2 m. while patient confined, then 25 g in 11 m.	Entire diseased breast sloughed off 4 m. after b.t. Fresh nodules in opp. breast. Died after b.t.
3	71	Retraction and ulcer nipple for 5 yrs	Lt nipple destroyed by ulcer. Small tumour beneath nipple. Fixed supraclav. and axillary nodes.	21 g per week for 9 m. Total 756 g.	Stationary over 13 m. Death 13 m. after b.t.
4	40	Radical amp. lt breast 2 yrs. ago, then x-ray therapy. X-ray therapy for recurrent nodule 8 m. ago	Extensive lesions thorax both sides. Nodes rt axilla and rt side neck.	21 g per week for 8 m. Total 672 g.	Slight diminution in lesions. Treatment nausea and vertigo.
5	53	Lump rt breast 4 yrs. Local mastectomy and post-op. x-ray therapy	Menopausal. Recurrence mastectomy area, 11 × 16 cm. Rt supraclavicular nodes. Metas. rt lung.	21 g per wk. for 3 m. Total 252 g.	No alteration in recurrence. Growth of metastases. Died 14 m. after b.t.
6	48	Radical amp. 9 yrs ago. Nodules in scar 1 yr. ago	Skin recurrence 13 cm diam. Hard supraclavicular node. Spheroidal-cell carcinoma.	21 g per week for 18 m.	Within 5 m. ulcer nodules epithelized. Fresh peripherally. Metas. in vertebrae and nodes during treatment.
7	63	Lump rt breast; x-ray therapy, then radical amp.	Multiple nodules chest wall; hard supraclavicular nodes. Spheroidal-cell carcinoma.	14-21 g per week for 15 m. Total, 980 g.	After 10 days regression marked. In 3 m. disappeared. In further 3 m. recurrence. Treatment maintained. Metas. in lungs. Death 17 m. after b.t.
8	55	Lump rt breast 1931, tr. radium 1932; recurrence 1942	Recurrence over sternum 5 cm diam. Lt supraclav. node.	31 g weekly. Total 756 g. in 6 m.	Extension of disease. Died 11 m. after b.t.
9	48	Amp. r breast Jan., 1941; x-ray therapy Oct., 1941, to skin nodules. Disease advancing	Intradermal carcinoma chest wall. Nodes axillae and supraclavicular regions. Scirrhus carcinoma.	21 g per week. Total, 279 g. in 2 m.	Died, local extension and metas. 5 m. after b.t.
10	63	Lump rt breast, ulcer, 1939. X-ray therapy palliative, poor response	Ulc. tumour breast, fixed axillary nodes. Spheroidal-cell carcinoma.	21 g per week. Total, 588 g. in 7 m.	No change during treatment.
11	60	Lump lt breast, uncertain duration. Ulcer 1941	Ulc. tumour. Hard supraclav. and axillary nodes. Spheroidal-cell carcinoma.	21 g per week. Total, 420 g. in 5 m.	No regression. Died 6 m. after b.t.
12	52	Lump rt breast and both axillae. X-ray therapy, incomplete resolution, July, 1941	Post-menopausal. Large mass rt breast and axillae. Extensive skin involvement.	21 g. per week. Total, 420 g. in 5 m.	Possibly slight local improvement. Lesions developed. Died 8 m. after b.t.
13	53	Recurrent nodules after radical amp. lt. breast	Nodules lt chest wall, axilla, and supraclav. region. Scirrhus carcinoma.	18 g. per week. Total, 429 g. in 6 m.	No regression. Not followed after 6 m.
14	65	Radical mastectomy, then x-ray therapy, 1941	Recurrence in scar; deposits lt axilla and both supraclav. regions.	21 g per week. Total, 336 g. in 5 m.	No regression. Alive, but lesions advanced.
15	49	Radical mastectomy, 1936. X-ray therapy to recurrence. Temp improvement	Recurrent carcinoma lt supraclav. and axillary nodes. Metas. dorsal vertebrae. Scirrhus carcinoma.	21 g per week for 3 m. Total uncertain.	No regression. Alive but deteriorating.
16	39	Recurrent carcinoma lt breast. Radium and x-ray therapy	Large mass lt breast and rt axilla. Scirrhus carcinoma.	21 g per week. Total, 630 g. in 7 m.	After stopping treatment, severe metastases. Lesions stationary; total observation 15 m.
17	54 (male)	Radical amp. lt breast, 1939. X-ray palliative therapy local recurrence	Two nodules in op. scar lt chest. Metas. lt. femur and ischium.	21 g per week. Total, 228 g. in 3 m.	Disappearance of nodules after b.t., recurrence next 6 m. Metas. in sacrum. Died 11 m. after b.t.
18	65	Lump rt breast 2 yrs. Ulcer 1 yr.	Ulc. mass 11 × 13 cm. Nodes supraclav. region and both axillae. Spheroidal-cell carcinoma.	21 g per week. Total, 189 g. in 9 weeks.	Mass reduced to 9 × 10 cm. Lung metastases during treatment.
19	52	Lump lt breast	Mass filling whole lt. breast. Large ulcer area; nodules lt chest wall; nodes axilla and supraclav. region. Scirrhus carcinoma.	21 g per week. Total, 250 g. in 4 m.	Lesion advanced during treatment.
20	56	Ulc. lump rt breast; recurrence after x-ray therapy	Tumour 10 × 9 cm whole rt breast; ulcerated. Nodes rt. pectoral region.	21 g per week. Total, 1,000 g. in 9 m.	Tumour shrank to 6 × 5 cm. Ulcer small and healed. 7 m. after b.t. ulcer enlarged and healed after, tumour enlarging, then slowly. Slight vaginal bleeding and nausea.
21	63	Radical amp. for carcinoma lt breast, 1932. Recurrence over sternum	Ulc. mass 7 × 4 cm, 4-5 cm deep. Spheroidal-cell carcinoma.	15 ccm dispersion of triphenylchloroethylene by injection in 5 m.	Lesion much flattened, area ulcerated. Cervical metas. 4 m. after b.t., then x-ray therapy. Nausea during treatment stopped.
22	63	Lt breast "shrinking" for 2 yrs	Whole lt breast involved. Nodes lt supraclavicular area. Lung metastases.	9 ccm. dispersion of triphenylchloroethylene by injection in 3 m.	Lesions progressed. Died 6 m. after treatment.

regression. No evidence was obtained to suggest that the drug will prevent the development of metastases. On the contrary, the impression was gained that the malignant cells become in time progressively more resistant to the inhibitory effects produced by the drug at an earlier stage. Thus only one of the cases has shown prolonged arrest, and the ultimate course of the disease has been in no way altered in the remaining patients,

nodules and masses, followed by epithelization of the skin. In exceptional cases the degree of response was considerable. One of these (Case 1) is illustrated in Fig. 1. Biopsy material was examined in 4 of the cases showing regression of the primary tumour. All were highly cellular types, as were also 2 of the 3 cases which maintained a stationary condition, the remaining case being of scirrhus type.

iere would seem to be a greater sensitivity to the action of estrogen in highly cellular than in scirrhous carcinomata (No. 18, spheroidal-cell carcinoma) serial biopsy treatment revealed the disappearance of mitoses and atrophy in the staining affinities of the cells the appearance did not resemble those seen after irradiation. The

some degree of regression. Relief of pain seemed a real finding in 4 cases—Nos 6, 10, 17, 21.

2. Miscellaneous Cases

This series consisted of 30 cases of advanced malignant disease other than carcinoma of the breast. They comprised

TABLE II—14 Cases treated with Stilboestrol

Case	Previous History	Condition at Beginning of Treatment	Date Treatment Started	Dose of Stilboestrol	Result of Treatment
2	Rt. radical mastectomy 1939. H.V. therapy to recurrence Dec. 1941–Sept. 1942. Further recurrence Dec. 1942.	General condition good. Multiple skin nodules scar area chest clear.	Dec. 2, 1942.	276 mg. intra-muscularly over 3½ months.	Deposit in manubrium developed during treatment. Nodules became bluish ulcerated and later scabbed.
3	Lump in lt. breast noticed 1919. Ulcerated 1934. Ray therapy to numerous areas rt. and lt. breasts chest wall and regional nodes Jan. 1939 to Aug. 1942. Recurrent skin nodules Dec. 1942. No section.	Multiple nodules and induration scattered over rt. and lt. chest wall and sternum. Ray chest—fluid at left base.	Dec. 22, 1942.	410 mg. intra-muscularly over 3 months.	Fresh nodules developed. Nodules became more raised and bled red. Uniform scabbing followed. Biopsy. Nodule showed highly cellular carcinoma of anaplastic type. Local area of necrosis present at centre of nodule. General condition deteriorated. Died 4 m. after onset of treatment.
12	Lump in lt. breast noticed Oct. 1939. Treated H.V. therapy Oct. 1940. Diathermy excision res. dual growth April 1941. H.V. therapy to recurrence Dec. 1941 and Oct. 1942. Further ray therapy Dec. 1942. Section. Undifferentiated columnar-cell carcinoma.	Multiple nodules lt. chest wall. Underlying diffuse oedema from axilla across midline to rt. breast which was widely infiltrated and fixed.	Dec. 30, 1942.	676 mg. intra-muscularly over 6 months.	In 1 month the rt. breast was softer. Oedema of chest wall had diminished. Nodules were paler, softer and smaller. This condition was maintained for 6 weeks after which the local condition progressed. New crops of nodules developed.
40	Lump in lt. breast noticed Mar. 1941. Treated ray therapy Mar. 1942. Recurrence Nov. 1942. Biopsy. Anaplastic carcinoma.	Ulcer lt. breast 7.5 x 3.2 cm. Regional nodes not enlarged. Ray chest—multiple second day deposits.	Dec. 22, 1942.	199 mg. intra-muscularly over 2 months.	Ulcer increased in size throughout treatment.
31	Complained of pain rt. hip Sept. 1942. Ray pelvis—large second day deposit pelvis.	Lt. breast—mass 3 x 3 cm. firmly fixed to deep structures. Rt. axilla—2 firm nodes 1.5 cm. across. Pubis—localized tenderness.	Jan. 23, 1943.	262 mg. intra-muscularly over 7 wks. 252 mg. orally in 6 wks. H.V. therapy to pubis concurrently.	Breast—slow increase in size of tumour with development of an adjacent skin nodule.
49	Lump in breast noticed Sept., 1939. Treated H.V. therapy 1940. Recurrence Oct. 1942, treated H.V. therapy. Further recurrence Jan., 1943.	Lt. breast—residual mass. Rt. breast—mass 12.5 cm. across. Skin adherent. Fixed deeply. Skin nodules over sternum.	Feb. 10, 1943.	450 mg. intra-muscularly over 5 weeks.	Tumour rt. breast progressed. Lt. breast—condition stationary. Secondary deposits in skull developed.
47	Mass lt. breast noticed July, 1940. Hard nodes rt. axilla and rt. supraclavicular regions. Treated ray therapy July, 1941 and Oct., 1942. Recurrence Jan., 1943. No section.	Rt. breast—skin diffusely infiltrated by growth. Rt. side neck—plaque of skin nodules 10 x 6 cm.	Feb. 15, 1943.	433 mg. intra-muscularly over 7 weeks.	Slow progress of disease.
60	Lump in breast noticed June 1942. Treated ray therapy Oct. 1942. Recurrence Jan., 1943. No section.	Rt. breast solid with growth but no deep fixation. Skin densely infiltrated. Reddened nodule 2 cm. across above nipple. Ray chest—many large secondary deposits. Lungs. Rt. axilla—hard fixed mass 5 cm. across. Nodules rt. chest wall.	Mar. 23, 1943.	660 mg. intra-muscularly over 4 weeks.	Mass rt. breast and rt. axilla increased in size. General condition deteriorated.
61	Radical mastectomy 1935. Recurrence 1943. Treated ray therapy Oct. 1943. Recurrence Dec., 1943. No section.	Nodules rt. chest wall.	Dec., 1943.	1 mg. daily 3 mths orally.	Many fresh skin nodules developed. Now in local hospital.
57	Lump in breast noticed Aug. 1941. Treated ray therapy Aug. 1942. Radical amputation in 1942. Recurrence Sept., 1943. Section. Highly cellular intra-duct carcinoma.	Nodules rt. chest wall rt. axilla, and rt. supraclavicular fossa.	Dec., 1943.	1 mg. three times a day orally for 4 months. Still under treatment.	After 2 months nodules flatter but size unaltered. In a further month nodules practically gone. After 4 months two fresh nodules developed.
64	Lump in breast 1942. Untreated.	Mass lt. breast 12 x 10 cm. with central ulceration. Mass lt. axilla 6.5 x 4.0 cm.	Feb., 1944.	15 mg. weekly intramuscularly and 1 mg. daily orally. Still under treatment.	In 2 weeks ulcer dry. In 12 weeks mass lt. breast 6 x 5.5 cm. Mass lt. axilla 3.5 x 2 cm. (Fig. 3). Biopsy. Spheroidal-cell carcinoma.
60	Lump in breast 1937. Grew steadily and ulcerated through skin. Ray therapy 1938. Recurred 1939, treated by radium implantation. Recurred 1940.	Ulcer 6 x 6 cm. fixed to muscle. Section. Cellular carcinoma of pavement-cell type.	Sept., 1943.	21 mg. weekly by mouth. Total of 315 mg. in 3½ months.	By Dec., 24 ulcer reduced in size to 3 x 2 cm. By April 15 two tiny patches ulceration 2 x 1.5 cm. and 1.2 x 1 cm.
67	Lump in breast noticed Oct., 1943.	Bright red mass lt. breast 9 x 8 cm. fixed to skin and muscle. Large lt. axillary node. Section. Papillary adenocarcinoma (malignant intraductal pattern).	Feb., 1944.	42 mg. weekly by mouth. Total of 438 mg. in 8 weeks.	Breast mass 7 x 7.5 cm. flatter and purplish. Axillary node not changed in size. Slight nausea, gain of 4 lb. in weight.
63	Radical mastectomy for carcinoma rt. breast 1936. In 1940 noticed lump in breast, and enlarged axillary and supraclavicular nodes. Palliative ray therapy 1940 and 1942. Extensive recurrence Oct., 1943.	Massive involvement en cuirasse back and front of chest. Section. Adenocarcinoma invading subcutaneous tissue.	Feb. 1944.	42 mg. weekly by mouth. Total of 378 mg. in 9 weeks.	Lesions progressed during treatment and general condition deteriorated.

ilar changes in this case are shown in Fig. 2. Case 17, which a marked response was obtained, is of special interest being the only male in the series.

The secondary signs of drug action included nausea, pigmentation of the mammary areola, uterine bleeding, improved appetite, and gain in weight. One or more of these changes occurred with special frequency in the group of cases showing

carcinomata of the skin, maxillary antrum, urinary bladder, ovary, rectum, and testis, with reticulo-endothelial growths, and one example each of chronic myeloid leukaemia and chronic lymphatic leukaemia. The period of treatment varied between 1 and 16 months. In nearly every case the drug seemed to have no effect on the course of the disease, although side-effects occurred in some. In other cases treatment was

terminated on account of the patient's being transferred to other hospitals, or referred for tumour excision or x-irradiation. Two cases which showed undoubted partial regression of the tumour merit special comment.

Case 1: Male aged 74; Carcinoma of Bladder.—The general condition was poor when treatment began. The patient complained of frequency of micturition, passage of blood in the urine, and shooting pains in the back and at the base of the spine. Cystoscopic appearances were typical of carcinoma of the bladder, and x-ray examination revealed a secondary deposit in D. 10. The bladder tumour was apparently slow in growth, since a second cystoscopy after 3 months showed little change. Treatment with triphenylchloroethylene was then begun, and was followed by a rapid improvement of the general condition. After 2 months a third cystoscopy showed marked amelioration of the local condition, with almost complete regression of the primary tumour. At this time tissue for diagnosis was taken through the suprapubic route, and doubtful areas in the bladder were fulgurated. An extract from the pathological report (by Dr. L. M. Hawksley) reads: "In the deeper part of the subepithelial connective tissue and in the fibromuscular tissue focal collections of squamous carcinoma cells, which are definitely identifiable as such, though of viable appearance in only one or two places, have undergone almost complete necrosis." The total dosage of triphenylchloroethylene administered was 760 g. over a period of 9 months. The patient died from circulatory failure 11 months after the beginning of treatment. Necropsy confirmed that viable tumour cells remained in the bladder wall after the disappearance of the primary tumour.

Case 2: Male aged 60; Carcinoma of Prostate.—In this case, admitted on account of frequency of micturition and later complaining of shortness of breath and fleeting chest pain, investigation with uroselectan revealed enlargement of the left kidney, with poor function, and a large filling defect in the bladder on the left side. X-ray examination suggested the presence of multiple secondary deposits in the bony pelvis, and in the following weeks similar deposits were recorded in the whole of the dorsal spine, in the ribs, femora, and humeri, and in the lungs. Cystoscopy showed enlargement of both lobes of the prostate, with a large papillomatous mass in the left wall of the bladder. Bladder capacity was much reduced (residual urine, 2 oz.). Biopsy at first gave no undoubted evidence of malignancy, but a second specimen (tissue from bladder removed through cystoscope 11 weeks after starting treatment with triphenylchloroethylene) was reported upon as follows by Dr. Hawksley: "Sections show intact and regular but thinned surface epithelium directly overlying a densely cellular mass of columnar-cell adenocarcinoma of prostatic type, in which well-formed gland lumina occur frequently in the solid cell masses. Although no signs of degenerative change are found, the tumour cells show an unusual absence of evidence of nuclear activity, no mitoses having been seen in the numerous sections examined, and the large, spherical nuclei showing a striking uniformity of size and structure."

Treatment with triphenylchloroethylene had been started on June 9, 1941, and soon produced side-effects (bilateral mastitis and oedema of the ankles) attributable to oestrogen action. Within 3 months the total dose administered exceeded 100 g., and the daily dose had reached 8 g. (maximum). The total dose after 6 months was 700 g., following which the daily dose was decreased (to 3 g.) on account of occasional nausea. During treatment there occurred a decrease in the frequency of micturition and some betterment of the general condition, which after 8 months was regarded as considerably improved. There was, however, no unequivocal radiographic evidence of change in the skeletal deposits, as judged by comparison, after repeated examination, of the various regions involved; but the prostate itself was described as "not obviously enlarged" after 13 months, when a total of 1,346 g. of triphenylchloroethylene had been administered. The plasma acid phosphatase values showed a distinct tendency to increase (from 17 units to 47 King-Armstrong units per 100 ml. over 15 months). The case was then transferred for treatment with stilboestrol in place of triphenylchloroethylene, and is included as Case 6 in a paper by Watkinson *et al.* (1944).

In this series of cases of malignant disease other than carcinoma of the breast, treated with triphenylchloroethylene, the number showing any degree of response was very small, and it may be noted that two of those chosen for comment represented types which might reasonably be expected to possess some special sensitivity to the action of oestrogens. Yet this is not invariably the case, and it is probable that a small proportion of tumours, not derived from tissues of any characteristic or obvious endocrine function or susceptibility, may give a similar response.

B. Triphenylmethylethylene

Four cases of carcinoma of the breast and 3 cases of Hodgkin's disease received treatment. The first group (all in

advanced stages of breast cancer) were treated for two months or longer by intramuscular injection of the drug, and only one case (pathologically a spheroidal-cell carcinoma) showed any response. This took the form of flattening of the lesions and the development of a blue coloration of the nodules in the skin. In the four cases, total dosage of the drug varied from 1.4 to 3.8 g.

The main points arising during the treatment of the cases of Hodgkin's disease, in two of which biopsies and serial blood counts were taken, were as follows.

Case 1.—A woman aged 42 presented enlargement of the submaxillary, cervical, and inguinal lymph nodes and multiple opacities in both lungs. A biopsy specimen from a node was diagnosed as Hodgkin's disease. When treatment began the blood count was: red cells, 4,580,000 per c.mm.; white cells, 10,000 per c.mm.; total lymphocytes, 1,000 per c.mm. After one month (in which 12 g. of triphenylmethylethylene was given intramuscularly) the blood count had fallen to: red cells, 2,750,000 per c.mm.; white cells, 5,000 per c.mm.; total lymphocytes, 140 per c.mm. The tumours themselves showed no response.

Case 2.—A boy aged 15 showed enlargement of the liver to the level of the umbilicus, of the spleen to that of the anterior superior iliac spine, and involvement of the cervical and hilar nodes. His general condition was very poor. He lived for 2½ months, and during this time received 242 g. of the drug by mouth. After 1 month both liver and spleen were notably smaller, and remained so until accurate observation was no longer possible owing to the development of gross ascites. No diminution took place in the size of the cervical or mediastinal nodes. Conclusions based on the blood picture are not possible, since two transfusions of whole blood were given; but no remission occurred during the period of observation. Necropsy revealed destruction of the pancreatic parenchyma by sarcomatous tissue, in view of which it was thought necessary to designate the condition as malignant—viz., Hodgkin's sarcoma or polymorphic reticulum-cell sarcoma.

Case 3.—A male aged 20 presented enlargement of a single group of cervical lymph nodes. Neither the spleen nor the liver was palpably enlarged. Over a period of 1 month 28.9 g. of triphenylmethylethylene was administered by mouth and 8.6 g. by intramuscular injection. During this time the mass in the neck increased in size. The effects on the blood picture seen in Case 1 of this series were not reproduced, both the red cell and lymphocyte counts remaining stationary. The case was then referred for x-irradiation, when the lesions proved to be radiosensitive.

C. Stilboestrol

Table II summarizes the details relating to 14 cases of carcinoma of the breast treated with stilboestrol: the most favourable response is shown in Fig. 3 (Case 11). Whether or not by chance, this small series provided a slightly lower proportion of cases showing any marked effect in the shape of changes in the growth and behaviour of the tumour. Assuming such changes to be related wholly to the oestrogenic activity of a given compound, there is no reason to suppose that the repeated administration of stilboestrol, which affords the advantage of effective action in very low dosage, will be less effective in producing them than is continued treatment with triphenylchloroethylene, but rather the contrary. In a few of the present cases treated with triphenylchloroethylene or triphenylmethylethylene administered orally, Mr. F. L. Warren was able to recover from the faeces over 90% of the dose given in a measured period (usually 24 hours). This indicates that the drug absorption is relatively inefficient, and probably highly so when compared with stilboestrol. There remains the possibility that some advantage may accrue from the use of compounds of exceptionally long duration of action (as judged by the persistence of their oestrogenic effects): several such compounds are now available, and this suggestion is being explored.

It is clear that the cases now reported afford no contribution to effective therapy, but they are probably sufficient in number to set the subject, as it stands at present, in a fair light. The results, although illustrating well the special difficulties inherent in the problem, have considerable fundamental interest, and at least provide an incentive to further investigation.

Summary

73 cases of advanced cancer received treatment with the synthetic oestrogens triphenylchloroethylene, triphenylmethylethylene, or stilboestrol.

FIG 1—Case 1 (Table I) *Carcinoma of Breast*. The primary lesion (A) at May 20, 1941, and (B) at Oct 29, 1941, after treatment with triphenylchloroethylene

FIG 2—Histological section, Case 18 (Table I). Above—Before treatment with triphenylchloroethylene. H and E $\times 300$. Below—After treatment for 1 month. Note irregularity in size shape, and staining of nuclei. H and E $\times 300$. Sections stained together

Of 22 cases of late malignant disease of the breast treated with triphenylchloroethylene (usually in doses of 3 to 6 g per day), 10 showed a significant although temporary retardation or even partial regression, of the growth of the tumour. No evidence was obtained to suggest that the drug will prevent the development of metastases. The initial effect of treatment in these cases passed off comparatively rapidly, and only one has shown prolonged arrest, the ultimate course of the disease being in no way altered in the remainder. The degree of retardation was less than could be expected from local palliative irradiation.

Of 30 cases of advanced malignant disease other than cancer of the breast (including carcinomata of the skin, maxillary antrum, urinary bladder, ovary, rectum and testis, with reticulo-endothelial growths and leukaemia) and similarly treated with triphenylchloroethylene, only 2 (carcinoma of the bladder carcinoma of the prostate) showed undoubted partial regression of the tumour.

Of 4 cases of mammary cancer and 3 cases of Hodgekin's disease treated with triphenylmethylethylene (usually by intramuscular injection) only one (spheroidal cell carcinoma of the breast) showed even a temporarily favourable response.

Of 14 cases of carcinoma of the breast treated with stilboestrol (by intramuscular injection or by mouth over a period of several months), 5 showed alterations in the growth and behaviour of the tumour similar in nature to those produced by triphenylchloroethylene.

Serial biopsies in a few cases with a marked clinical response showed histological alterations (diminution of mitosis rate, variations of staining behaviour, and necrotic changes) of a type not resembling the changes following irradiation.

The secondary signs of drug action included nausea, pigmentation of the mammary areola, mastitis in the male, uterine bleeding, and oedema of the lower extremities. One or more of such changes

FIG 3—Case 11 (Table II) *Carcinoma of Breast*. The primary lesion (A) at Feb 7, 1944, and (B) at May 22, 1944, after treatment with stilboestrol

occurred with special frequency in cases showing some degree of tumour regression. Several of these cases also manifested improved appetite, gain in weight, and diminution of pain.

This investigation has been supported by grants, for which we express our thanks, from the British Empire Cancer Campaign and the Anna Fuller Fund. We are also indebted to the Medical Com-

mittee of the Royal Cancer Hospital (Free) for permission to publish details of those cases under their charge, and to Imperial Chemical Industries Ltd. (Dyestuffs Division) for supplies of triphenylchloroethylene and triphenylmethylethylene.

ADDENDUM.—CYTOLOGY OF SERIAL BIOPSIES FROM A CASE OF CARCINOMA OF THE BREAST TREATED WITH STILBOESTROL

BY

P. C. KOLLER, D.Sc., Ph.D.

The following is a summary of the cytology of serial biopsies from Case 11 (carcinoma of the breast, Table II, above) taken during a period of markedly favourable response (tumour regression) after treatment with stilboestrol.

Biopsy I. Before Treatment: Feb. 7, 1944

In respect of nuclear morphology two main cell types could be distinguished in the resting stage. One is characterized by a nucleus which contains several Feulgen-positive chromocentres (the potentially dividing cell). The other has a nucleus with one large or several small nucleoli (the differentiated cell). The proportion of potentially dividing cells in different regions of the biopsy material was found to vary between 12.5 and 27.3%. The division rate was determined in four cell populations (600 cells in each) taken from different regions of the specimen: in these the division rate was found to be 2.3, 5.2, 5.6, and 7.5%. Synchronous division of three or four tumour cells was frequently observed. Chromosome behaviour and spindle formation were normal. The highest incidence of degenerated cells was 2.5%.

Biopsy II. March 10, 1944 (Treatment started Feb. 9, 1944)

Nuclear and cytoplasmic changes were observed. Cells were found with one or more vacuoles in the nucleus, which latter gave a weakly positive Feulgen reaction. The frequency of such cells varied between 4 and 7.5% in different regions. Other abnormal cells were seen with deeply staining cytoplasm. The division rate was apparently lower in this biopsy specimen as compared with Biopsy I: the highest division rate found was 4.6%. In some dividing cells chromosomes were seen lying off the equatorial plate, and these were shorter and thicker than usual. While there appeared to be a decrease in division rate, a significant increase was observed in the proportion of degenerated cells. In one region it was found to be 12.5%. The morphology of the degenerating cells differs from that of cells degenerating as the result of x- or gamma-radiation.

Biopsy III. During Treatment: April 25, 1944

The number of cells showing nuclear and cytoplasmic alterations was further increased. Division rate was estimated to vary between 2 and 5.6%. Apart from chromosome lagging at anaphase in a few dividing cells, no other mitotic abnormalities were seen. The frequency of degenerating cells was about the same as in Biopsy II.

Biopsy IV. During Treatment: May 29, 1944

The biopsy material shows marked alterations. The division rate was increased and regions were encountered with 14.3% of cells in division. Synchronous division of several adjacent cells was very frequent. The chromosomes of cells in mitosis were thick and short, they failed to form an equatorial plate at metaphase, and were altered in the cells. Cells with multipolar spindles were also encountered. The proportion of degenerating cells was found to vary between 7.3 and 16.3%. While the cellular abnormalities and the various stages of cell necrosis observed in the second and third biopsies indicated that cell degeneration is brought about by nuclear vacuolization, evidence was obtained from this fourth specimen that cell degeneration may also be due to a breakdown of the mitotic mechanism. The cytological evidence thus suggests that the primary effect of stilboestrol in this case may be localized to the nucleus of the tumour cell.

REACTIVE HYPERINSULINISM

CASE REPORT, WITH A DISCUSSION OF THE DIFFERENTIATION FROM ISLET TUMOUR

BY

F. T. G. PRUNTY, M.D., M.R.C.P.

(From the Department of Pathology, St. Thomas's Hospital Medical School)

The condition known in this country as "hypoglycaemia" (Cambridge, 1924) is described under the term of "hyperinsulinism" or "dysinsulinism" in America, according to the manifestations encountered—dysinsulinism implying an erratic under- and over-secretion of insulin (Harris, 1934). According to this terminology, hyperinsulinism would not include hypoglycaemia due to hepatic damage. The conditions here to be discussed are those in which the pancreatic activity is mainly at fault, and therefore exclude those due to other glandular dyscrasias and hepatic disease. It is the object of this communication to draw attention to a condition which may be termed "reactive hyperinsulinism," as opposed to hyperinsulinism due to overactivity of the pancreas as a result of tumour of the islets, malignant or benign. The term "reactive hyperinsulinism" is to be preferred to that of "functional hyperinsulinism" of Conn (1940), since the word "functional" has other less well defined associations.

Case Report

A professional man aged 56 complained of attacks consisting of a sinking feeling during the preceding five years and

of continual tiredness for four years. He had had three attacks of arthritis, mainly affecting the larger joints, in the course of ten years. The family history was noteworthy (see genealogical chart). The patient's mother had died of diabetes mellitus, but the father was a healthy man, and lived to the age of 84. The eldest brother had renal glycosuria, and his eldest son has been found to have glycosuria. A second brother has also had glycosuria for many years, recently having had an operation for cataract. There are also a healthy brother and two sisters.

The patient stated that for the last four years he had had a continual feeling of tiredness accompanied by considerable difficulty in concentrating. During this period his work had greatly increased and his hours had been long, with short intervals for meals. For five years he had had acute attacks consisting of a sinking feeling in the epigastrium and intense weakness, followed by a cold sweat. He was forced to sit down during the attacks, but never fainted. After the attack had passed off his appetite was ravenous. The attacks always occurred in the afternoon or early evening, about three hours after the last meal. It appeared that his wife had been in the habit of "fortifying" him daily with a large tea consisting mainly of carbohydrate, including a great amount of honey or jam. Furthermore, the greater the quantity of such food consumed the greater the severity of the subsequent attack. The attacks passed off spontaneously with rest for about ten minutes or on taking carbohydrate. Their frequency was variable, six weeks sometimes elapsing between them, at other times two occurring in a week. In general their frequency and severity had increased with the passage of time. Occasionally exercise—e.g., gardening—brought on an attack, but only at the time of day already mentioned. Usually he could take considerable exercise and little food without getting symptoms. He had had no polydipsia or polyuria and no headache. He had lost one stone in weight in three years.

On examination the patient was not obese. There were no physical signs and no evidence suggestive of glandular or hepatic disease. Circumstances did not permit of special investigations of liver function, but the blood-sugar curve does not conform to the type seen in hepatic disease. There was no glycosuria.

Investigations of Blood Sugar

A month before he was seen reports on his blood sugar were: p.m. (during an attack), 48 mg. per 100 ml.; 14 days later, 8 a.m. (before breakfast), 71 mg. per 100 ml. At 8.30 a.m. a carbohydrate breakfast was taken; at 10 a.m. the blood sugar was 1 mg. and at 11 a.m. 66 mg. per 100 ml., the value at 12 noon being the same.

While in hospital the blood sugar was found to be 85 mg. per 100 ml. on two occasions before breakfast. Immediately after lunch the value was 87 mg. per 100 ml. The patient then took a rapid 10-hour walk in hilly country, producing a moderate degree of fatigue, and at the end of this time the blood sugar was 97 mg. per 100 ml. The accompanying Graph shows the results obtained with

Continuous line represents glucose-tolerance test: 50 g. glucose orally after 12 hours' fast. Dotted line represents insulin tolerance: 6 units of insulin intravenously, fasting.

glucose-tolerance and insulin-sensitivity tests, the patient at the time receiving a full ward diet. There was no glycosuria during the glucose-tolerance test. Typical symptoms of one of the patient's hypoglycaemic attacks occurred when the blood sugar had fallen to 48 mg. per 100 ml., and persisted for one hour. The symptoms consisted of blurring of vision, the distant appearance of near objects, difficulty of finding words in speech or writing, inability to concentrate, coldness and clamminess, and a sinking feeling in the pigastrium. The insulin-tolerance test showed a slight increase of sensitivity to insulin. During this test there was another typical hypoglycaemic reaction when the blood sugar had fallen to 40 mg. per 100 ml. The symptoms disappeared without intervention, and there was no question of the patient's approaching a comatose state.

A diagnosis was made of reactive hyperinsulinism due to excessive insulin response resulting from the stimulus of administered carbohydrate. The patient was advised to cut down the consumption of carbohydrate at tea and replace this with protein or fat—e.g., in the form of an egg—if necessary. Having reduced the consumption of potato for lunch and dinner, together with the omission of jam, honey and curtailment of bread-and-butter and cake at tea, the patient has experienced no further attacks over a period of twelve months. This is in spite of the fact that his work has continued as before.

Discussion

The chief differential diagnosis in this case is from organic hyperinsulinism due to tumour of the pancreatic islets, which is present might be malignant. A search of the literature reveals that there is a lack of criteria for establishing this diagnosis except especially Harris, 1936-7). However, there are apparently certain points that may be of diagnostic value. For instance, Conn (1940) considers that the presence of a low value for the fasting blood sugar before breakfast, the diet being normal, is a point strongly in favour of organic disease. It is well known that there is no relation between the blood-sugar level and the severity of a hypoglycaemic attack, although many of his cases do in fact have such attacks at this time. The second point for special examination is the shape of the glucose-tolerance curve. Conn and Conn (1941) consider that in "functional hyperinsulinism" the blood-sugar level shows a precipitate fall after a large amount of carbohydrate. Examination of the case reports of Finney and Finney (1928), Feinier *et al.*

(1935-6), and Fraser *et al.* (1938) show, for example, sugar-tolerance tests of the "plateau type." Whipple *et al.* (1941) in an analysis of 17 cases due to tumour found that the curve had a decided trend towards the diabetic type, this presumably being a manifestation of dysinsulinism. Their average figures showed a resting value below normal, with a subsequent persistent blood-sugar level of about 150 mg. per 100 ml. for a period of two to three hours. However, in their report two cases diverged from this type and gave low flat curves—a finding also observed by Conn and Conn (1941).

There are fewer reports available on the value of the insulin tolerance. Hartmann and Jaudon (1937) found an unusual sensitivity to insulin in newborn hypoglycaemic children whose mothers were diabetic, the hypoglycaemia being due to prolonged foetal islet stimulation. Furthermore, the findings of Fraser *et al.* (1938) in a case of islet tumour are so striking, and in such contrast to those in the present case, that they merit further study. Those authors found that, although the sensitivity to insulin was approximately normal, there was no tendency for the spontaneous recovery of the blood sugar within two hours. The injection of insulin in the fasting state was a reliable means of producing a severe hypoglycaemic reaction which only terminated on the administration of adrenaline or glucose. The finding of the adrenaline sensitivity is opposed to the views of Wilder *et al.* (1927)—who were supported by Allen (1941)—that resistance to adrenaline is a diagnostic point in favour of tumour. Cammidge and Poulton (1933), commenting on the case reported by Griffiths and de Wesselow (1933), pointed out that this test may be difficult to interpret.

A final point that may be of value in the differential diagnosis is the severity and irregularity of the symptoms. In general it appears that the more severe they are, without any tendency to spontaneous alleviation if glucose is not given, and the more irregular their onset, the more likely is organic disease. Conn (1940) and Harris (1936-7) both gave criteria indicating the necessity for laparotomy, the latter author suggesting that the inability to control the attacks by diet within a few weeks should be taken into account. Allen (1941) considered that the ability to control symptoms by means of a high-protein diet is indicative of but a mild degree of insulin excess. However, in view of the malignancy of carcinoma of the pancreatic islets and the inoperability consequent upon the occurrence of metastases, it is clearly essential to establish criteria for laparotomy requiring as short a period of observation as possible.

The following summarizes the features of the present case for contrast with the foregoing points:

1. Absence of low fasting blood sugar before breakfast and after exercise.
2. The marked post-prandial fall in blood sugar during the glucose-tolerance test, accompanied by the onset of symptoms of hypoglycaemia, together with an instability of the blood-sugar-regulating mechanism for a period of two hours. This finding is in close agreement with the history obtained of the most severe attacks occurring after the largest amounts of carbohydrate had been taken for tea.
3. A slight increase in the sensitivity to insulin, the occurrence of a typical hypoglycaemic attack after intravenous administration of insulin, and the spontaneous return of the blood-sugar level to normal limits with disappearance of symptoms.
4. The mildness and ease of control of the symptoms by means of reduction in carbohydrate intake.
5. The family history of diabetes and renal glycosuria.

In connexion with the last of the above points the case of MacPherson (1941) may help to throw some light on the aetiology of these attacks. His case showed a sugar-tolerance curve resembling that in the present case. In addition to this his patient had renal glycosuria—a condition recognized as occurring with, and possibly playing a part in the production of, "functional hyperinsulinism" (Conn, 1940). MacPherson suggested that two of the precipitating factors in his case were irregularity in meals and hard work. In the present case it appears from the history that there was some definite relation of the onset of symptoms to increasing severity of work and to increase of worry. Although humoral mechanisms are involved in the control of blood-sugar levels, Wachaup (1933) and Conn (1940) indicated that imbalance of the autonomic

nervous system may have a bearing on the production of "functional hyperinsulinism." Cori (1931) in an extensive review concluded that vagal impulses play a part in the finer regulation of the insulin production, and Cannon *et al.* (1924) have shown that nervous control of the adrenal medulla via the splanchnic nerves ensures a rapid adrenaline response.

It can well be appreciated how the continuance of abnormal stress in a susceptible individual may give rise to abnormality or instability in the control of these opposing impulses by the hypothalamic region. The terminal stages of the glucose-tolerance test is illustrative of this.

Summary

A case of "reactive hyperinsulinism," manifest by an excessive post-prandial fall of the blood-sugar level, is described. Points in the differential diagnosis from hyperinsulinism due to tumour of the pancreatic islets are discussed.

My thanks are due to Dr. H. Gardiner-Hill for his interest and permission to publish this case, and to Dr. C. Ede for assistance, especially with the history.

TRAUMATIC RUPTURE OF THE AORTA

BY

GILBERT FORBES, B.Sc., M.D., F.R.F.P.S., F.R.C.S.Ed.

Lecturer in Forensic Medicine at the University of Sheffield;
 Police Surgeon to the City of Sheffield

The following case of rupture of the aorta due to a blow on the epigastrium presents clinical and pathological features interesting enough to be placed on record.

Clinical History

The patient was a farmer, aged 37, who was described by his relatives as being in robust health. He had no relevant medical history, but his family doctor had observed that he had a very high threshold for pain. On Jan. 20, 1944, he went ploughing at 1 p.m., and at 3 p.m. left the field to call at a neighbouring farmhouse for a drink of water. He there complained that shortly before that time his plough had struck a stone, and the plough handle, rearing up, had hit him somewhere in the region of the praecordium. The blow had shaken him badly, and from statements he made to various people it appears that immediately after the accident he felt very ill, owing presumably to shock; but he soon recovered, continued to plough till about 4 p.m., and made no further reference to the accident. He returned home at 5 p.m., when he complained of pain in the left side of the chest radiating through to his back. It was observed that he was cold, clammy, and pale, and he had to go to bed. He was examined later the same evening by his doctor, who found that his temperature was 100° F. and that friction could be heard in the cardiac area. The patient made no reference to the accident, and his doctor was in complete ignorance of the incident till after the man died. He passed a restless night because of chest pain, and vomited three times. Next morning the pyrexia had disappeared, and though he still complained of pain he did not seem to be particularly ill. His condition remained much the same till late afternoon, when he died suddenly within a few minutes of sitting up in bed to drink a cup of tea.

Post-mortem Findings

The deceased was well built and there was no external evidence of injury. No bones were broken. There was an area of bruising in the areolar tissue of the anterior mediastinum, and the bruising extended up the right side of the neck as far as the level of the larynx in the line of the great vessels and sterno-mastoid muscle. The pericardial sac was distended with blood, which had infiltrated

the wall, particularly in the region of the base of the heart. On the posterior wall of the first part of the aorta there were three tears in the vessel—one just above the valve cusps, a second at the beginning of the arch, and a third midway between the first two. The upper tear was half an inch and the others each a quarter of an inch in length. All the tears were oblique to the transverse axis of the vessel, but were not parallel to one another. The aorta was not dilated, and the only abnormality was some early atheroma, which appeared as small patches hardly elevated from the general level of the intima and free from calcification and ulceration. The heart weighed 28 oz. (793.5 g.), but the hypertrophy was evenly distributed throughout all the chambers; there was no dilatation; all the valves were competent and their cusps healthy. The heart muscle was of excellent tone and free from all sign of disease, both on gross examination and microscopically, but the individual fibres were hypertrophied. The coronary vessels were capacious, and on the left one there were a few small patches of early atheroma, but quite insufficient to interfere with the blood supply. The right coronary artery was healthy.

In the peritoneal cavity there was a little slightly blood-stained serum. On the posterior abdominal wall some haemorrhage could be seen shining through the peritoneum in the region of the pancreas. The left half of the body and tail of that organ were haemorrhagic, but no fat necrosis was anywhere observed. The other structures in this cavity were uninjured. The only abdominal disease found was an early hydronephrosis of the left kidney, and, though the entire urinary tract was dissected, no satisfactory explanation was discovered for this abnormality. There was no sign of chronic nephritis or any significant abnormality in other structures.

Comment

Contusion and rupture of the pancreas are relatively rare injuries. Vance (1928) quotes Gall to the effect that they occur in 4.4% of all visceral injuries, and most other authors agree with this figure. The pancreas lies in such a position that it could only be injured, in the absence of an open wound, by some hard object coming forcibly in contact with the epigastrium and crushing the gland against the body of the second lumbar vertebra. It is possible, however, that the view of Boesch (1921) is correct—namely, that the gland may frequently be injured without the condition being recognized during life. This case tends to support that view, as the patient made no complaint referable to the abdomen and was neither rigid nor tender in that region. Furthermore, the fact that fat necrosis was not present indicates that the pancreas was not contused and not ruptured, and it seems likely that the condition might have resolved and remained unrecognized had the patient not sustained other more serious injuries which proved fatal.

It is clear, then, that the handle of the plough struck him a deep, powerful blow in the epigastrium. There were no injuries of any kind to the thoracic wall in the shape either of subcutaneous or muscular bruises or of fractures of the ribs or sternum, and it is almost inconceivable that a relatively sharp object like a plough handle could strike that region with enough force to produce the internal injuries described without leaving some mark on the soft tissues or the thoracic cage. It follows, therefore, that the damage to the aorta must have been produced indirectly by transmission of the force through the diaphragm. This thesis is supported by the fact that the anterior mediastinal tissues were contused in the absence of more superficial damage, the bleeding being no doubt due to the rupture of small vessels consequent upon the sudden dislocation of the pericardial sac. The heart is suspended in the pericardium by the aorta and superior vena cava, but is given basal fixation by the inferior vena cava and the structures of the lung roots. Its potential mobility is strictly limited in all directions, and it seems unlikely that rupture of the aorta alone could occur, due purely to displacement of the heart and traction on the vessels, by a force applied to the diaphragmatic surface of the heart from the abdomen.

Ruptures of the aorta are relatively frequent, but when they occur it is nearly always as a result of crush injuries, in which the osseous structures of the thoracic wall may or may not be fractured, depending largely on their elasticity. The tear is usually transverse, and is located just above the aortic valve cusps. It is due to a force thrusting the heart downwards and tearing it from its points of suspension. In these cases, as a rule, the tear is complete and the outcome immediately fatal. Partial ruptures—which become complete later—are more uncommon, and may arise in the absence of trauma if the

requisite predisposing factors are present Peery (1942) has recorded the finding of healed partial tears in the first part of the aorta. According to him, partial tears are usually encountered in the ascending portion of the arch, are usually transverse or oblique and are rarely longitudinal. An essential predisposing factor, in Peery's opinion, is severe hypertension of long standing and he is not certain that there need be any abnormality in the wall of the vessel. Microscopical sections from the aorta taken near the lesion, but not including it, usually do not show any recognizable abnormality. Arteriosclerosis is probably not a cause for this condition, since the tears seldom occur through an atheromatous plaque or ulcer. The precipitating factor in most cases is exertion, which, by raising the already elevated blood pressure, exceeds the pressure the aortic wall can stand and rupture occurs.

Another predisposing condition is the presence of coarctation of the aorta, in which the vessel tears below the constriction, presumably owing to the increased pressure in that part of the artery (Moragues, Moore, and Rossen, 1942).

A few cases of partial rupture of the aorta have been recorded in which trauma was the immediate cause. In Heller's (1904) case the partial tear was due to a heavy burden falling on a man's chest. In the case reported by Oppenheim (1918) clinical manifestations followed a blow by a falling piece of granite. Nordlander (1925) and Oppenheim (1918) both referred to the occurrence of ruptured aorta in aviators falling from a high altitude.

The present case is unusual, if not unique, because of the method of production of the damage to the vessel. This man had a grossly hypertrophied heart, and, though his blood pressure was never recorded and there were no symptoms or other post mortem changes to suggest it, he probably suffered from essential hypertension, though the fact that he had followed a strenuous occupation may have been partly responsible for the hypertrophy. There is no such lesion now recognized as idiopathic cardiac hypertrophy in an adult, and, in the opinion of Kugel and Stoloff (1933), it appears doubtful whether there is such a condition in infants and young children, as some workers maintain. The heart, as stated, weighed 793 g. According to Aschoff (1924) the normal heart weight in men is up to 355 g, while Parkinson (1936) quotes Evans to the effect that the upper limit is 390 g. By either of those standards this heart was grossly hypertrophied, and though many hearts weighing more have been reported (Strong and Munroe, 1940; Rosenow and Smith, 1939, and Royster, Lisa, and Carroll, 1941) some other factor in addition to essential hypertension has usually been present to account for the hypertrophy. The mechanism of production of the aortic lesions therefore seems to have been the increased pressure in that vessel. The sudden compression of the heart must have further raised the already high pressure in the left ventricle and aorta to such a degree that the vessel wall was incapable of withstanding it and partial rupture ensued.

The clinical symptoms in cases of partial rupture of the aorta are always indefinite, and the literature does not seem to record a case in which this condition has been diagnosed ante mortem. According to Peery (1942), "the most common symptom is a choking sensation or a feeling of suffocation. Dyspnoea may come on suddenly and continue for some time. Pain is also a frequent symptom, and may be stabbing or tearing, although pain is less frequent and less severe when dissection supervenes immediately. Occasionally cough, haemoptysis, and fever are the presenting symptoms, and may be associated with pain of pleuritic type. The most important physical finding is undoubtedly the presence of heart murmurs. These may be either systolic or diastolic, and are usually best heard in the aortic area. The systolic murmur is as a rule harsh, and is probably due to vibration, in the blood current, of the abrupt shelf like edge of the tear or to eddying of blood over the small pouch between the lips of the tear. In a considerable proportion of cases however, dissection of the aorta occurs days, weeks, or months later, with the usual manifestations of the condition. In other cases the clinical picture becomes one of aortic regurgitation with congestive heart failure." In the present case there was no immediate pain referable to the thorax, and two hours elapsed before pain started. Probably during that time dissection was not occurring

and the acute pain in the left side of the chest radiating through to the back became manifest when dissection through the media began to develop. Final rupture 26 hours after the original injury is in keeping with other cases reported and, as in a proportion of these, it occurred after some mild exertion—in this case sitting up in bed.

It is interesting to speculate what the outcome might have been if the patient had stopped work after the injury and gone to bed. Perhaps the intimal tears might have healed, as happened in the cases reported (Peery, 1942).

Many cases have been recorded in which hypertension has been associated with a unilateral renal lesion of some sort, and hydronephrosis is one of the conditions mentioned. Baggenstoss and Barker (1941) have reviewed the literature and reported a series of their own cases. Their series is short and, they admit, insufficient to draw statistical conclusions in the case of hydronephrosis, but they nevertheless tend to the opinion that this condition does not appear to influence the onset of hypertension. This aspect of the case is mentioned merely for the sake of completeness, in view of the work of Goldblatt (1940) and of Wilson and Byrom (1939) on the relationship between unilateral renal ischaemia and hypertension.

Summary

The clinical and pathological features of a case of rupture of the aorta due to a blow on the epigastrium are discussed.

Gross cardiac hypertrophy and essential hypertension are considered as factors in the mechanism of production of the aortic lesion.

The aetiology and symptomatology of partial rupture of the aorta are reviewed.

My thanks are due to Dr James McCartan of Sheffield for particulars of the clinical history of the patient.

A FATAL CASE OF PURPURA AFTER SULPHAPYRIDINE

By

SHEILA SHERLOCK,* M.B.ED., M.R.C.P.

Research Assistant

AND

J. C. WHITE, M.B., M.R.C.S.

Assistant in Pathology

(From the Departments of Medicine and of Pathology, British
Postgraduate Medical School)

An opportunity recently occurred of making observations on a case of acute purpura occurring during the course of sulphapyridine therapy for pneumonia. As we have found records of only 18 cases in the literature, this seems to be one of the rarer complications of sulphonamide administration. For this reason we report the essential details of the case.

Case Report

On Oct. 13, 1943, a patient aged 32 became ill with a febrile condition diagnosed as pneumonia. Sulphapyridine was administered outside hospital, 30 g being given in seven days. The immediate response was satisfactory, but five days after cessation of treatment a rise of temperature gave cause for anxiety. Recrudescence of pneumonia or empyema was considered. Sulphapyridine therapy was restarted, 4½ g being given during the next five days. The malaise and pyrexia, however, persisted. It was noted that the temperature rose after each dose of sulphapyridine. On Oct. 23 there was slight

* Working on behalf of the Medical Research Council

epistaxis. The patient was admitted to hospital on Oct. 30 for investigation.

Apart from trench fever in the last war the patient had enjoyed good health. He had not been subject to asthma, hay-fever, or urticaria; he had never taken sulphonamide drugs previously; and there was no personal or family history of a haemorrhagic diathesis. He was a heavy beer-drinker. An obese heavily-built man, he showed some difficulty in maintaining attention. Mucous membranes were pale. Temperature was 101.6°. The fundus oculi had some arterial thickening, but there were no haemorrhages. The nose was bleeding. There was much oral sepsis. B.P. 205/120. The chest revealed signs interpreted as those of a resolving right lower lobe pneumonia. Spleen and liver were not palpable. There was no enlargement of peripheral lymph glands.

By Oct. 31 the temperature was subsiding, and on Nov. 1 had become normal. B.P. was now 160/110. On this day an extensive purpuric eruption appeared on the palate, arms, and legs. Epistaxis persisted, and blood was oozing from the gums. Three times during the day he vomited coffee-ground material giving a positive benidrine reaction. The urine, normal in quantity, had become frankly blood-stained. The ankles presented pitting oedema.

On Nov. 2 his condition showed further deterioration. Purpura was even more gross, and blood was flowing freely from the nose and mouth. There were many submucous haemorrhages in the mouth, and in the tongue they were particularly well marked. Haematemesis and haematuria persisted. Sternal puncture was performed, and compatible blood was transfused through the site of puncture. As the procedure was started the patient complained of a bursting sensation in the head: 2½ hours later he was in coma. Respirations became laboured and gurgling, and blood-stained saliva was coming from his mouth. The fundus oculi, which earlier in the day had been clear, now showed numerous flame-shaped haemorrhages. There was a left hemiplegia, and plantar responses were bilaterally extensor. B.P. was 260/140. In a further 2½ hours coma had become profound. Fundal haemorrhages were more pronounced and blurring of the disk margins was observed. There was a flaccid paralysis of all the limbs. A finger-prick, made 2½ hours before, was still bleeding freely. Death rapidly supervened.

Investigations

X-ray chest, Nov. 1:—Left ventricle enlarged. Aorta unfolded. The appearances in the lung fields suggested bilateral recent resolving pneumonia. *Sputum* showed a scanty growth of *Strep. pneumoniae* and *neisseriae*. *Haematology*, Nov. 1:—Erythrocytes, 2,500,000 per c.mm.; Hb (Haden), 47% (733 g. per 100 c.cm.); C.I., 0.94; reticulocytes, less than 0.1%. Leucocytes, 10,000 per c.mm.: 3,200 lymphocytes, 6,000 neutrophil polymorphs, 500 eosinophils, and 300 monocytes. Platelets, 150,000 (direct method, using Lempert's modification of Kristenson's technique). Bleeding time (Duke's), 36½ min. (normal 2-5 min.); coagulation time (Lee and White), 27 min. (normal 5-8 min.); clot retraction, 1 hour (Macfarlane), 19% (normal 44-66%). Capillary resistance test by a positive-pressure method indicated very marked fragility. Smears of sternal marrow revealed no grossly abnormal features, except some preponderance of the myeloid elements. Megakaryocytes were present (0.4%), and these appeared normal. The leuco-erythrocytic ratio was 4.1. *Biochemistry* (7 hours ante mortem):—Plasma urea, 214 mg per 100 c.cm. Plasma uric acid, 7.3 mg./100 c.cm. Plasma proteins, total 6.4 g./100 c.cm., of which 3.3 g. was albumin, 2.6 g. globulin, and 0.5 g. fibrinogen. Plasma bilirubin, less than 0.5 mg/100 c.cm. Plasma sulphapyridine: free 2.1 mg/100 c.cm.; total 4.44 mg./100 c.cm.

Urine Analysis—On admission the urine was acid in reaction and contained albumin. The specific gravity was 1008. The centrifuged deposit showed only occasional leucocytes. Haematuria appeared on Nov. 1 and persisted. A sample passed 6 hours before had a specific gravity of 1007, and albumin was present. There was no urobilinuria. Microscopy of the deposit revealed a number of red blood cells. Leucocytes were 6 per h.p. field, and there were very numerous coarsely granular casts.

Necropsy—(34 hours after death; Dr. C. Keith Simpson.) The heart showed subpericardial, myocardial, and endocardial haemorrhages. Coarse purpuric haemorrhages were present throughout both lungs, causing extensive coarse nodular consolidation. No superimposed infection could be established. There was extensive purpura throughout the alimentary tract, mainly subperitoneal and with but little actual bleeding. The liver showed some purpura. Pulp haemorrhages were present in the spleen. Both kidneys were shot with innumerable purpuric haemorrhages resulting in virtual infarction. The renal pelvis, ureters, and bladder contained no crystalline deposits and there was mild purpura only. The brain showed coarse purpuric haemorrhages into the cortex, into the white matter, including a vast area of confluent purpura in the right frontal lobe, and also into the ventricular system.

Histology (J. C. W.)—*Lungs*:—The essential lesion was a widespread haemorrhagic consolidation, mainly confluent. Intervening

areas were emphysematous, acutely oedematous, or collapsed. Infiltration of the alveoli by inflammatory cells was observed only at the periphery of the haemorrhagic areas. There was no unresolved pneumonia. The pulmonary capillaries were congested, particularly subpleurally. In some capillaries the endothelial lining cells were swollen. Myocardium revealed only scattered haemorrhages. *Liver* showed no gross pathological change. *Spleen*:—The splenic pulp contained scattered areas of haemorrhage, particularly in the subcapsular region. Moderate amounts of haemosiderin were demonstrated in the splenic pulp. *Kidneys*:—There were multiple haemorrhages. These were especially numerous in the subcapsular region, and formed wedge-shaped extensions into the deeper parts of the cortex. Focal areas of round-celled, mainly plasma cell, infiltration were scattered throughout. These bore no relation to any particular structure. The glomeruli were free from pathological change apart from slight thickening of the capsular basement membrane and occasional distension of the capsular space by red blood cells. There was considerable degenerative change in the epithelium of both convoluted tubules. A few of the collecting tubules contained acidophil hyaline material but no crystals. The interlobular arteries showed hyperplastic thickening and the afferent arterioles a slight degree of hyalinization. There was some increase in renal interstitial tissue, and large numbers of effete red cells were present. Little increase in collagen or reticulin could be demonstrated. Haemosiderin was practically absent.

Sections of femoral bone-marrow showed no architectural change.

Diagnosis

This patient's fatal illness could be attributed to the effects of sulphapyridine. The original lesion was a pneumonia, and the bleeding tendency did not become apparent until 16 days after the onset of this illness. At necropsy the pneumonia had resolved. A bleeding diathesis may be associated with nitrogen retention. In our case the plasma urea was 214 mg. per 100 c.cm. Though he was a hypertensive subject, the kidneys showed only moderate vascular changes. It would therefore appear more likely that the recent severe haemorrhagic changes in the kidney were responsible for impairment of function. In addition, the effects of gastro-intestinal haemorrhage would play a part in producing azotaemia (Black, 1942). The haemorrhagic state in our patient, therefore, was probably the cause rather than the result of the uraemia.

Discussion

The pathogenesis of sulphonamide purpura is a subject for conjecture. The drug is sometimes directly toxic to the bone-marrow. The structure of the sulphonamide drugs is similar to that of benzol derivatives having a known myelotoxic action. The occurrence of agranulocytosis and aplastic anaemia during sulphonamide medication is well known. In such cases thrombopenia associated with the aplastic anaemia (Meyer and Perlmuter, 1942) and the agranulocytosis (Dolgopel and Hobart, 1939) has been recorded. However, the red and white cell elements are usually well maintained in the peripheral blood in the acute purpuras associated with sulphonamide therapy, the former showing only a slight fall consequent upon haemorrhage, and the latter often being raised. Bone-marrow studies in our case revealed abundant megakaryocytes and increased cellularity, particularly of the myeloid elements. Similar findings have been reported (Markel and Rike, 1939; Russell and Page, 1940; Losada and Fernandez, 1942; Gorham *et al.*, 1943). More probably the purpura results from a generalized vascular defect.

In recent years the importance of the capillaries in the pathogenesis of purpura has been stressed (Mackay, 1931; Macfarlane, 1941; Scarborough, 1943). In all the 7 recorded cases of purpura following sulphonamide therapy in which the resistance of the capillaries was tested a marked fragility was noted. In 9 out of 12 cases the bleeding time was prolonged. In 4 of the reported cases, including our own, the platelet count, although low, had not been reduced to the level usually associated with bleeding in essential thrombocytopenic purpura. Scarborough in a recent personal communication mentioned a case of thrombocytopenic purpura following the local application of sulphathiazole ointment in which, after recovery from the acute phase, and when the platelet level was restored to normal, application of sulphonamide drugs to the skin led to a marked fall in capillary resistance in parts remote from the site of application. There was no significant change in the platelet count. The effect on the vessels may be due to hypersensitivity. If drugs are administered in two courses hypersensitive phenomena are more likely to occur. In our case

the drug was given for 7 days; then a 5-day interval was allowed to elapse before restarting it. It was only on the second occasion that the supposed intolerance became apparent. The only other instances of spaced dosage associated with purpura are recorded by Russell and Page (1940), Harries (1942), Werner (1942), Gorham *et al.* (1943), and Hurd and Jacox (1943). In 8 cases the administration was uninterrupted. Drug hypersensitivity may remain after recovery. Hurd and Jacox found that giving a small dose of sulphathiazole or sulphadiazine to their patient caused a marked fall in the platelet count with an increased bleeding time and a positive tourniquet test. Rosenfeld and Feldman (1942), however, were able to give a later course to their patient with no further purpura.

In the reported cases no member of the sulphonamide group of drugs seems exempt as a causative agent, and sulphanilamide, sulphapyridine, sulphathiazole, and sulphadiazine have all been held responsible.

The high mortality of this condition—8 out of 9 cases proved fatal—makes early recognition essential. The first clinical sign is nearly always epistaxis. If this or other spontaneous bleeding is discovered in a patient receiving sulphonamide drugs the administration should be stopped immediately and a bleeding time and capillary resistance test done. Adequate transfusion of fresh blood is probably the best line of treatment.

Summary

A fatal case of acute purpura occurring in the course of sulphapyridine therapy in pneumonia is recorded.

The pathogenesis of this condition is discussed. Vascular lesions as a basis for its causation are emphasized.

In view of its high mortality a watch for extraneous bleeding should be made in all cases receiving sulphonamide drugs.

We wish to express our thanks to Prof. J. H. Dible and Dr. J. McMichael for much helpful criticism. The necropsy findings are reported by kind permission of Dr C. Keith Simpson.

HAEMOGLOBIN LEVELS IN THE WOMEN'S AUXILIARY AIR FORCE

BY

FL. LIEUT. SIMON YUDKIN, Ph.D., M.B., M.R.C.P.

R.A.F. Institute of Pathology and Tropical Medicine, Halton

Between May, 1943, and April, 1944, a survey of haemoglobin levels among various groups of W.A.A.F. personnel was carried out. The main purpose of the survey was to determine whether the average haemoglobin levels showed any significant change during service in the W.A.A.F. In addition some of the results have been incorporated into the report of the nation-wide survey of haemoglobin levels initiated by the Haemoglobin Survey Committee of the Medical Research Council, whose report will shortly be published.

Plan of Experiment

The following groups were chosen: (1) W.A.A.F. personnel arriving to join the Service in May and June, 1943. (2) W.A.A.F. personnel attending an N.C.O.s' course in June, 1943. (3) W.A.A.F. personnel at a bomber station and a training wing in Sept., 1943. At each station all the personnel were asked to volunteer for the test, and, except at the training wing, almost all volunteered.

The girls completed a card giving information required by the Haemoglobin Survey Committee of the Medical Research Council (see Appendix). The haemoglobin level was then

determined on a sample of blood from the ear, using the technique suggested by the Committee and a standardized Haldane haemoglobinometer.

Results

Most of the W.A.A.F. were between 18 and 25 years of age and all between 18 and 35. The distribution of the haemoglobin levels in the groups of W.A.A.F. examined is given in the accompanying Table according to length of service. Separate analysis of the results for the N.C.O.s and the W.A.A.F. personnel from the bomber station and training wing shows no significant difference, so these groups have been combined.

It is seen that all the groups who had been in the Service for more than six months had significantly higher haemoglobin levels than the group of W.A.A.F. just entering the Service, but that after six months to a year there is no further improvement. The coefficient of variation, however, becomes steadily smaller with longer service. The mean value for all those who had been in the Service for more than six months is 103.05, with standard deviation 9.12. The results have also been analysed according to trade. Some of the trades are represented by very few W.A.A.F., so that comparison has been possible only for a few. There is no significant difference between the results for cooks and butchers, motor transport drivers, clerks, aircraft hands (general duty), and telephone operators.* Analysis of the results according to age shows no significant differences in the age groups represented (18-35 years).

Table showing Distribution of Haemoglobin Levels of W.A.A.F. according to Length of Service

Hb %	On Entry	Length of Service				Total More than 6 Mths.
		1-1 Yr.	1-2 Yrs	2-3 Yrs	More than 3 Yrs	
126-	—	1	2	—	—	3
121-	—	1	2	—	—	3
116-	6	2	9	6	1	18
111-	6	5	9	16	2	32
106-	41	8	18	22	5	53
101-	80	10	26	25	5	66
96-	118	4	25	32	7	64
91-	143	14	12	15	1	43
86-	87	2	3	7	0	12
81-	52	0	1	2	1	4
76-	10	1	0	1	—	2
71-	8	—	0	—	—	0
66-	3	—	0	—	—	0
61-	2	—	1	—	—	1
56-	0	—	—	—	—	—
51-	0	—	—	—	—	—
46-	1	—	—	—	—	—
Total	559	48	103	127	24	307
Mean value %	94.84	102.46	104.10	102.71	101.62	103.05
Standard deviation	9.22	9.90	9.51	8.47	8.26	9.12
Coeff. of variation	9.72	9.66	9.14	8.25	8.13	8.85

Forty of the W.A.A.F. from Group 1 were retested after ten months' service. The mean value of the haemoglobin levels of these girls on entry was 98.8 (standard deviation 8.32); after ten months the mean improvement was 4.25. This improvement is statistically significant (4.25 ± 1.70). The level reached is similar to that in the other groups with more than six months' service.

Discussion

Choice of Groups.—Almost all the girls in each group volunteered, so that there was practically no selection within the groups. The group of N.C.O.s were drawn from many stations to attend the course, and so constituted a fairly random sample of W.A.A.F. population so far as location is concerned. On the other hand, they were all training as N.C.O.s and were to that extent selected. They were presumably of more than average intelligence and their period of service was comparatively long; there was probably also some slight selection by trade. The group of W.A.A.F. from the bomber station and training wing, however, although selected as to location, were not selected by rank or trade. As the results for this group are not significantly different from those for the N.C.O.s,

* A smaller survey carried out on 82 W.A.A.F. aircraft fitters and 59 W.A.A.F. electricians showed the mean Hb of these to be 106.92 (standard deviation 10.2) and 106.87 (standard deviation 9.1) respectively. These figures are significantly higher than the mean for the general W.A.A.F. population after more than six months' service (difference 3.82 ± 0.91).

it appears that the selection in the two groups did not affect the accuracy of the estimate of mean haemoglobin levels. It is possible that the group of W.A.A.F. which entered the Service some time ago might be differently constituted as regards social status, etc., from those which were entering later. The results for the new entrants are, however, similar to those of other groups of the population (M.R.C. report, 1944), and it seems very unlikely that earlier entrants could have had haemoglobin levels so much higher. Furthermore, the haemoglobin levels of the 40 girls of this group retested after ten months were by that time similar to those of other groups of more than six months' service.

Accuracy of Results.—Errors in the estimation of haemoglobin by the method used in this survey arise from three sources: inaccuracies in the apparatus, errors in collecting the sample of blood, and the error in matching. The apparatus was standardized and the appropriate correction applied to all readings. These corrected values are those given in the Table. The error in collection has been estimated by collecting samples from the ear and vein of 25 subjects and measuring the haemoglobin level in the usual way. This test showed that the samples from the ear were approximately 4.2% higher than those from the vein. It is probable that the levels as estimated from venous blood are more accurate. The error in matching was assessed by a test instituted by the Haemoglobin Survey Committee. The full results of this test are published in the report of the Committee; it may be stated, however, that I tended to read too low, as did most of the others taking part. The average correction to be applied in the ten samples estimated was approximately +4.4%. It is probable that a similar correction may be applied to all the results given in this report. The errors in collection and matching are similar in size but tend to alter the true values in opposite directions, so that the results given in the Table may be taken as being about the true values. The retesting of the 40 girls in Group 1 was carried out after the results of the matching test had been made known, and it was possible, therefore, that this error was being unconsciously corrected at the second test. A further 194 girls who had just come into the Service were therefore tested. The mean haemoglobin value of this group was 96.15 (standard deviation 10.0), which is not significantly different from that of the girls in Group 1 (difference 1.31 ± 0.817). It appears likely, then, that the error in matching was not being corrected and that the improvement in the 40 girls was real.

Normal Haemoglobin Values.—The mean haemoglobin level reached after six months' service is higher than any of the levels usually regarded as normal. The figure given by Price-Jones (1931) is 98.3%, and this has usually been accepted as the best estimate of normal averages. On the other hand, the value reached by the W.A.A.F. after six months' service (103% approximately) is well maintained without further improvement. This would suggest that the normal value is at least as high as this. It is possible that some of the W.A.A.F. with low values might not be consuming much of the Service diet and might be capable of showing further improvement; this would tend to make the mean value even higher.

Cause of Improvement.—The improvement is probably largely due to the high iron intake of women in the Service. The average intake per person per day is about 35 mg. (see Macrae, 1944); much of this iron comes from iron cooking vessels, which are rarely used in domestic cookery. What part is played by the intake of much protein of high biological value is not known, but there is little evidence of deficient intake of protein in the general population (H.M.S.O., 1944). It is doubtful if vitamin C intake plays any part in the improvement. The average ascorbic acid intake of W.A.A.F. personnel is about 25 mg. a day in the autumn and about 18 mg. a day in the spring (Macrae, 1944). It is probably at least as high among civilians, because domestic cooking methods are on the whole less destructive of this vitamin. Some slight improvement in average values may be due to the medical treatment of a few W.A.A.F. with low haemoglobin who develop symptoms during Service life.

Summary

The haemoglobin levels of W.A.A.F. personnel entering the service is about 95% (standard deviation 9.22) on the standard

Haldane scale. The haemoglobin level after six months service is about 103% (standard deviation 9.12). This level is reached in six months to a year and is maintained thereafter. The error in collection results in readings which average approximately 4.2% too high, and errors in matching in readings which average approximately 4.4% too low. Correction for both these errors thus leaves the readings as given in the Table. It is probable that the "normal" mean value of women of this age group is at least 103%.

The improvement is probably due mainly to the high iron intake of W.A.A.F. personnel.

I am indebted to the commanding officers and W.A.A.F. administrative officers of the stations concerned and the W.A.A.F. personnel who took part in the test for their co-operation; to Dr. Bradford Hill for advice concerning the plan of the experiment and in the analyses of the results; and to Dr. Davies, pathologist at the Royal Gloucester Infirmary, for granting me laboratory facilities during May and June, 1943.

APPENDIX

Copy of Proforma Used in R.A.F. Haemoglobin Survey

Name.....	No.....	Serial No.....
Date of joining W.A.A.F.....	Age last birthday.....	
Home address.....	Married, Single, Widow.....	
Previous occupation and town of work.....		
Occupation of husband.....		
Mark with a cross the circumstances applicable before joining the W.A.A.F.		
a. Lived with family on civilian rations usually supplemented by regular meal (5 or more a week) at canteen or restaurant.....		
b. Lived with family on civilian rations usually supplemented by some meal (less than 5 a week) at canteen or restaurant.....		
c. Lived with family on civilian rations without supplementary meals as described or with some meals as follows (Give short description).....		
d. Lived in hostel, institution, or other communal life as follows (Give short description).....		
e. Other circumstances as follows (Give short description).....		
Serious illnesses during past six months ("Serious illness" if confined to bed for a week or more).....		
Were you a blood donor?..... No. of donations in past 2 years.....		
Date of last donation.....		
No. of previous pregnancies..... Date of end of last.....

Medical Memoranda

A Note on Red Hair, Rheumatism, Tuberculosis, and Bleeding

The question of rheumatism, red hair, and bleeding has been raised again in the *Journal* (July 1, 1944, p. 33), and the stimulating reply there given suggests that the following data are worth stating.

RED HAIR

Of late all patients with red hair who consulted me have been noted, and this report concerns 100 consecutive red-haired patients. The accompanying Table shows the conditions in which the red-haired were seen with any frequency. It is clear that only a small minority (6%) of patients with rheumatic fever had red hair. The 3% of pneumonia patients with red hair probably coincides with the incidence of red hair in the population dealt with. Hill and Allan (1929) found an incidence of 3.1% in London children. A larger series will be necessary before it can be affirmed that the incidence of red hair in rheumatic patients is substantially greater than that in pneumonia or in the general population.

Hill and Allan (1929) found that 6.4% of 562 rheumatic cases had red hair, but only 3.1% of 536 controls (percentages which I confirm). According to the contributor in the *Journal*, this difference in 500 patients is probably significant. Yet Hill and Allan concluded that there were no physical characteristics peculiar to rheumatic children, no doubt because they considered other colours of hair and also eye colour, and did not concentrate on red hair alone. Shrubbsall (1903) found that blond traits were associated with acute rheumatism and tonsillitis, and brunette traits with pulmonary tuberculosis and malignant disease. Yet pulmonary tuberculosis was the chief disease with red-haired sufferers among these 100 red-haired.

But in conformity with Shrubbsall I saw malignant disease in 2 red-haired patients only. It should be of value further to study the incidence of red hair in pulmonary tuberculosis, rheumatic fever, acute tonsillitis, purpura simplex, and epilepsy.

BLEEDING

The contributor to the *Journal* stated that he had no knowledge of any work on red hair and excessive bleeding. There is, however, evidence that rheumatic fever is associated with unusual (if not excessive) tendency to bleed. The tendency of rheumatic persons to nose-bleeding is discussed by Levine, Andren, and Homans (1930). Coburn (1933) found post-mortem evidence that rheumatic fever was associated with diffuse haemorrhagic changes. I (Davis, 1941, 1943) have given evidence of a special association between purpura simplex and rheumatism. I do not yet know whether this association is stronger in red-haired rheumatic subjects. Although many clinicians will have seen purpura in tuberculosis the association is relatively rare (Davis, 1943). It might also be worth while investigating this association in red-haired tuberculous patients.

Details of a Series of 100 Red-haired Patients (Diseases in which Red Hair was seen in more than 3 Patients)

Dis ease	Total Cases	Cases with Red Hair	Percentage of 100 Red-haired Patients
Pulmonary tuberculosis	296	23 (7.8%)	23
Rheumatic fever (past or present)	248	15 (6.0%)	15
Acute tonsillitis	162	12 (7.4%)	12
Pneumonia	270	3 (1.0%)	3
Purpura simplex	59	7 (12.0%)	7
Epilepsy	47	6 (13.0%)	6

COMMENT

Of 240 patients with rheumatic fever 6% had red hair, as against 3% of pneumonia patients and 7.8% of sufferers from pulmonary tuberculosis. Of a series of 100 red-haired patients, 15% were rheumatic, 23% were tuberculous, and 12% had acute tonsillitis. There is a special association between rheumatism and purpura.

I thank Mr J. R. M. Whigham, F.R.C.S., and the staff of St Andrew's Hospital for their help.

ELI DAVIS, M.D., M.Sc., M.R.C.P.,

Intussusception after Appendicectomy

The following case is recorded as a rare instance of intestinal obstruction after operation.

An otherwise healthy boy was admitted on June 22, 1944, suffering from abdominal pain and vomiting of 12 hours' duration. His temperature was 99.8° and pulse 120, and he was tender in the right iliac fossa. The same day I removed his appendix, which was long and inflamed. Nothing else appeared wrong, though in view of the pathological appendix I did not make a search. His temperature fell to 98.4° the next day. He was happy, free from pain, ate his meals, had his bowels open, and was apparently convalescent.

On June 29—the seventh day after operation—his condition changed. His appetite went and he was fretful, but he did not complain of any sudden or serious abdominal pain. His bowels were open for the last time on that evening. The next day he began vomiting, he had absolute constipation to enemas, and his abdomen was tender to palpation. The wound was well healed. I did not think I could feel any definite abdominal mass. Some mucus was passed per rectum, but no blood.

On July 1 his abdomen was distended and there was visible peristalsis. I opened the abdomen again, and found a large, fairly tight enteric intussusception in the ileum, about a foot from the ileo-caecal valve. With a little difficulty it was reduced. The gut was viable. There was no Meckel's diverticulum. The next day his condition was excellent. He was happy again, began taking light diet, and his bowels were opened regularly. His convalescence since then has been uneventful.

The question arises: Could he have had the intussusception when I removed his appendix on June 22, or was it initiated by the abdominal manipulations? It was reducible and viable nine days after the initial operation.

I wish to thank Dr. Geoffrey Dudley for permission to report this case.

THEODORE BLISS, M.B., B.S. Lond.,
Resident Surgical Officer, Corbett Hospital, Stourbridge.

Reviews

PHYSIOLOGY OF THE C.N.S.

Physiology of the Nervous System By J. F. Fulton, M.D., Sterling Professor of Physiology Yale University; formerly Fellow of Magdalen College, Oxford. Second edition. (Pp 614 38s) London, Oxford University Press

The appearance of the first edition of this book in 1938 marked an important phase in the current intensive study of the central nervous system, and was a most welcome addition to physiological literature. The second edition puts us still further in Prof. Fulton's debt, by bringing the subject well up to date, and introducing further improvements in the display of facts and figures.

Some of the chapters have been largely rewritten, and particular stress has been laid on the biochemical aspects of the subject, such as the significance of acetyl choline in relation to nerve transmission, and on the important developments of the method of following nerve impulses by recording the electrical variations from point to point. Important results of developmental research are incorporated, and also advances in our knowledge of cutaneous receptors, of the functions of the basal ganglia and parietal lobes. There is a chapter on conditioned reflexes by Dr H. S. Liddell, which gives an account of interesting work on sheep, and in general somewhat modifies the point of view taken by the Pavlov school.

A remarkable feature of the book is the splendid bibliography: one would expect a good list of references from Prof. Fulton, but this one is quite exceptionally valuable. The general get-up of the volume is excellent.

HEALTH SERVICES

The Nation's Health By Prof J. M. Mackintosh. Target for Tomorrow No. V (Pp 64, illustrated, 4s 6d) London The Pilot Press

A series of books under the general title of *Target for Tomorrow* is being published under the supervision of Sir William Beveridge, Dr. Julian Huxley, and Sir John Boyd Orr. The fifth volume in this series, by Prof. James Mackintosh, in 64 profusely illustrated pages, tells the general reader a good deal of the story and breathes the spirit of a reformer more interested, perhaps, in the wider problems of the public health than in those that beset the private individual when he seeks the advice of his family doctor.

The very short chapters are successively entitled: "Health: the Problem"; "Doctor: Patient and Health Insurance"; "Hospital, Consultant and Nursing Services"; "Maternity and Child Welfare"; "Other Health Services"; "The Problem of Health Administration"; "Medical Research"; "In Other Countries"; "Health: Plans and Opinions"; "A Target for National Health". The short text is pithy and informative, and the author has evidently relied on photographs to fill in the gaps he has left. It is not always clear why he has chosen the pictures he has: for example, in the 4½ pages given to "Hospital, Consultant and Nursing Services," 2½ are occupied by reproductions of Florence Nightingale in the military hospital at Scutari, Lister in a King's College Hospital in 1893 (in a charmingly old-fashioned group), and of one of the latest and brightest wards in "an up-to-date public hospital run by the London County Council." A lay person will no doubt say to himself, "The public hospital has it." But the comparison, if a comparison is intended, is unfair. To give one whole page to a photograph of a small boy cleaning his teeth does not really throw much light on the dental services of the country or on the problem of dental caries, and to give 4½ pages to illustrating the Peckham Health Centre seems a little out of balance in a book of this size. On the other hand, a full-page view of an occupied bedroom in West Ham says more about the evils of overcrowding than any number of tables, charts, or verbal description: this picture tells a story and drives it straight home.

The author may have been writing against time, and his book was already drafted when the Government issued its White Paper in 1944: he must be congratulated on the skill with which he met this awkward situation and on the excellent and concise summary he gives of the Paper. But we doubt whether members of the

public health service, of which he is a distinguished representative, would agree with him that the White Paper provides a solution for the "confusion in local health administration." It may, however, provide a solution for the "duality of the voluntary and public hospitals," but the solution is one that disturbs those who still cling to the idea that the voluntary hospitals of this country represent something that is of profound significance in our communal life. Prof. Mackintosh, discussing the organization of professional and hospital services, refers to the "obstinate traditions and habits of thought" of "these institutions": it appears—though this is not quite clear—that he refers to hospitals. Does this adjective "obstinate" reflect the ambitions of the reformer who sees little virtue in the continuity of history, and looks upon tradition as an obstacle and not as a guide? At all events, he seems to dispose quite easily of the tradition of freedom when he says of the Medical Appointments Committee which he believes should control the distribution of doctors, "they should be able, in addition, to divert medical men to areas where the number of doctors is insufficient."

In a last short note under the heading "Experiment and Research" he writes: "The Medical Research Council should continue to supervise this all-important side of the forward drive towards the health target, but under the general direction of the central health authority." Does Prof. Mackintosh suggest that the work of the Medical Research Council should come under the control of the Ministry of Health? We may recall that on the creation of the Ministry of Health in 1919 the direction of the M.R.C. was transferred to a Committee of the Privy Council when it ceased to be the Medical Research Committee established to administer the money for medical research provided by funds under the National Insurance Act. The secretary of the M.R.C. is also secretary of the Privy Council Committee for Medical Research, and this and the method of appointment to the M.R.C. safeguard it from too much State interference. We think Prof. Mackintosh's proposal would push the clock back, not on.

In a couple of pages the author describes with admirable brevity some points in the health services of the U.S.A., the U.S.S.R., and Sweden. Describing what happens in the U.S.S.R., he writes: "Under the Soviet Constitution citizens are guaranteed the right to medical treatment at the expense of the State, and they also receive maintenance in the event of loss of working capacity through illness. This general principle has made it possible to build up a comprehensive medical service at the expense of the State, which pays and employs all medical and auxiliary workers." No doubt this is the only way a comprehensive medical service can be built up under the Soviet Constitution, but we believe that it is possible to reach the same goal by different means under the British Constitution. Yet this short description of what is now done in Russia might almost be used to describe what the Government is proposing should be done in Great Britain.

MEDICAL PARASITOLOGY

Medical Parasitology By James T. Culbertson. (Pp 285. \$4 25 or 28s)
New York: Columbia University Press; London: Oxford University Press.

This book does not claim to be a complete treatise on medical parasitology. It has been written for medical men and medical dentists who have in no way specialized in tropical medicine, who in the future will require to know the fundamentals of the subject, since the intermingling of populations owing to the war and the increased facilities for travel will break down many of the barriers which have separated tropical from temperate diseases. It is increasingly realized that the sharp demarcation between the temperate and tropical countries no longer exists, and that many of the parasites and the diseases they produce which were regarded as peculiarly tropical will to an increasing extent be world-wide in their distribution. Accordingly the author has written this book primarily for medical men whose sphere of work is outside the Tropics. There is no lengthy description of the structure or development of the parasites, but enough information is given to make intelligible what is said under the headings of pathogenicity, immunity, diagnosis, specific therapy, and prophylaxis. The illustrations are simple and adequate, though in some cases

possibly a little sketchy. All the disease-producing protozoa and helminths are considered, as also the Arthropoda of medical importance. There is a useful appendix of the more important technical methods employed for the detection and examination of the various parasites; also an introductory section giving general consideration to the subjects of infection, epidemiology, natural and acquired immunity, diagnosis, specific therapy, and prophylaxis.

The book is undoubtedly a useful one, and more particularly so for those who are taking up the study of human parasitology for the first time.

THE BILIARY SYSTEM

Clinical Lectures on the Gallbladder and Bile Ducts. By Samuel Weiss, M.D., F.A.C.P. (Pp. 504; illustrated. \$5.50 or £1 14s. 6d.) Chicago: Year Book Publishers, Inc.; London: H. K. Lewis and Co.

This book presents an account of the anatomy, physiology, and diseases of the biliary system from the physician's point of view, together with the appropriate methods of examination and investigation. Surgical technique is completely excluded. The material is obtained in part from the author's experience, but even more from the literature, and it tends to fall between the two stools of the personal investigation and the full-scale review. The title "Clinical Lectures" is unfortunate in so far as it invites comparison with vivid writers such as Trousseau and Hutchison. The main faults of Dr. Weiss's book are that it is dull reading and that the reader is often given no guiding thread to find his way through the contradictory opinions that are quoted. The chapter on liver function tests, for example, has no broad discussion of the tests, no hint of the theories on which investigators have worked, no summing-up of the relative value of the tests, but merely a sequence of tests arranged without rhyme or reason. Neither pernicious anaemia nor acholic jaundice is mentioned in the index or in the text, though both diseases are often complicated by gall-stones. The book will be most useful to the physician preparing to give a lecture or present a case of biliary disease. It is too undigested for the student. It is well produced, with good illustrations, though it is a little difficult to see why a kneeling Venus should have been chosen as the model for surface markings and reflex disturbances; she is certainly not the gall-bladder type.

Notes on Books

Volume XII (1943) of the *Brompton Hospital Reports* (price 8s. 7d. post free from the Secretary of the hospital) contains 13 papers by members of the staff. Only two of these papers have not previously been published. Six articles deal with various aspects of tuberculosis. Mr. Price Thomas and Dr. Cleland discuss exhaustively, with excellent illustrations, the indications, technique, and complications of extrapleural apicectomy with thoracoplasty. In another paper, on the results of thoracoplasty, they show that the death rates have been materially reduced as increased experience has been gained in selecting cases and in operative technique; and that more expensive operations, employing mobilization, increase the prospects of cavity closure and sputum conversion, but they do not increase the mortality or risk of complications. In the paper prepared by Dr. A. Margaret C. Macpherson—"Childhood Infection and its Relation to Adolescent and Adult Pulmonary Tuberculosis: A Record of the Work of the Brompton Hospital Research Department during the last 14 Years"—it is stated that a shallow pneumothorax with only a short stay in hospital is the correct form of treatment for "symptomless adolescent pulmonary tuberculosis." Many tuberculosis workers will disagree with this. Among the articles dealing with subjects other than tuberculosis, attention should be drawn to the painstaking work of Dr. Foster-Carter on the anatomy of the bronchi; and all members of the medical profession will be interested in Dr. Hope Gosse's survey, "The Health of the Doctor." The volume also contains the hospital's medical reports for the years 1939-42, and an index of authors and a general index of Volumes I to XII.

In *Cape Horn Sunsets* (Mellifont Press Ltd.; 1s.) Dr. M. F. McElligott describes his experiences as a ship surgeon on a voyage to Australia, outward round the Cape of Good Hope and homeward round Cape Horn. The book is chiefly written in the form of a somewhat discursive diary, whose pages are freely sprinkled with the author's reflections and reminiscences.

CALSIMIL

Trade Mark

Calcium Sodium Lactate with Vitamin D

At all periods of the year the average intake of calcium is generally lower than is necessary for the maintenance of full health and for the promotion of normal growth and development. The calcium deficiency may be primary (lack of calcium in the diet) or it may be secondary and attributable to malabsorption or to inadequate retention. Such secondary deficiencies may result from lack of Vitamin D or of the provitamin, or from lack of sunshine, or from anomalies of absorption or diminished alkalinity of the blood which leads to excessive loss.

The administration of Calsimil provides the extra calcium needed in these deficiency states, and, in addition, it ensures the correction of any of the secondary causes of deficiency.

Calsimil should be taken during periods of deficiency by patients of all ages and as a routine during periods of special need such as infancy, adolescence and pregnancy. For these purposes Calsimil may be confidently recommended. Its form of presentation, palatable tablets of calcium sodium lactate with Vitamin D, ensures its acceptability to patients of all ages.

Details of dosage and other relevant information will be gladly supplied on request.

VITAMIN D

and its addition to infant milk foods

Just twenty years ago, the first of the standardised and concentrated vitamin products, 'Ostelin' vitamin D, was introduced in convenient form for exact use in mixtures and in drop doses. This was a notable achievement in the prevention and treatment of rickets. In 1928, this concentrate of vitamin D was added to the infant food, Ostermilk. And now, in 1944, the amount of vitamin D in Ostermilk has been increased to 700 international units in each reconstituted pint—a further contribution to the prevention of rickets. The earliest contribution to child welfare goes back to 1908 when the first dried-milk for infant feeding was introduced, a food which played an important part in the reduction of epidemic gastro-enteritis. All this important pioneering work in nutrition at the Glaxo Laboratories, inspired by the belief that nutritional disease is preventable, has had its effect on present-day standards and on present-day concepts of infant feeding. Research continues, backed by large technical resources, in the still unexplored fields of nutrition and disease.

GLAXO LABORATORIES LTD., GREENFORD, MIDDLESEX

IMPROVED CONTROL

IN DIABETES MELLITUS

Globin Insulin (with Zinc), 'Wellcome' brand, is a clear solution with an action which is quick in onset and moderately prolonged in duration. This feature gives improved control of the blood-sugar level in many cases of diabetes, enabling them to be satisfactorily maintained on a single daily injection.

VESALIUS THE MAN

The *De humani corporis Fabrica* of Vesalius, first printed at Basle in 1543, is the greatest single contribution to the medical sciences. Moreover it ranks among the most beautiful books of the sixteenth century with an assured place in the annals of draughtsmanship and of the wood-cutter's art. Its plan and execution, with those of its companion the *Epitome*, were completed within the astonishingly brief space of three and a half years. Its author was then but twenty-eight. Nought else by him is of even secondary scientific value. Without these twin books his career would be of little interest. Despite much research we have only meagre details of his life. The late Prof. Roth of Basle spent many years seeking details of his career, for which Roth's monograph of 1892 is still our chief source. It is a model of exact statement but quite fails to yield the picture of a personality. Beyond a few references in contemporary sources and half a dozen rather improbable traditional stories we have only Vesalius's own writings in which to discern him. For such reasons his other works are worth close examination.

Harvey Cushing applied himself during some forty years to the task of eliciting a picture of the real Vesalius from his writings and from direct and indirect references to them. He left his book about half finished. It exhibits extraordinary bibliographic skill and patience, and has been prepared for publication by Prof. Fulton, assisted by Dr. W. W. Francis.¹ Their modest reticence prevents us, as they would wish, from ascribing an exact share to either. In effect something like a quarter of their beautiful volume must be regarded as a pious memorial by these two scholars to their late colleague. Bibliography does not lend itself to detailed criticism. The proof lies in the use thereof. During several months we have referred repeatedly to this book, and testify to its completeness, convenience, and reliability. We discuss some of its information, treating the works of Vesalius in chronological order.

I. His first publication was a paraphrase of a Latin translation of part of a book by the well-known Arabic writer Rhazes, printed at Louvain in 1537. It may be regarded as a graduation thesis. In it we can ourselves discern neither originality nor promise nor deep scholarship. There is some evidence that it was mainly copied from a document in the possession of his family. That it appeared six times in its own century only proves once again that mediaeval medicine died hard. Perhaps it is not quite dead yet.

II. The *Tabulae sex*, printed at Venice in 1538, is a group of large anatomical sheets, three of the heart, great vessels, and generative organs drawn by Vesalius himself, and three of the skeleton drawn by the artist Calcar. Those by Vesalius

are highly traditional. We believe the figures of the heart and vessels to be based on animal anatomy and probably on that of a rhesus monkey. Those by Calcar are drawn direct from the skeleton of a youth of 18 articulated by Vesalius. They are a real advance on representations of the kind. All six plates have a running text that is at once a monument and a curiosity of anatomical nomenclature. To this text Cushing unfortunately gave no attention. The *Tabulae* were immediately copied by plagiarists. To them, on the other hand, Cushing gave more of his time and skill than their interest seems to us to warrant. He demonstrated, however, that the scheme spread very rapidly in German lands. Base imitations took the place of the original, which was not reprinted. Perhaps it was too large for convenient transit and too expensive for slender purses. Only two copies survive. The original figures were used for class demonstration. Vesalius added a drawing of the cranial nerves which has disappeared but is substantially represented in the *Fabrica*.

III. *The Institutes of Anatomy according to the opinion of Galen, for Students in Medicine, by Johannes Guenther of Andernach, edited, amplified and corrected by Vesalius*; Basle, 1538.—Guenther (1505-74) was a good Greek scholar whose laborious life was largely spent in making over-hasty translations of works of Galen into Latin. He came to Paris in 1527. Some six years later Vesalius began to study under him. The master had a deep influence on his pupil. We could wish that he had transmitted his own clear manner of writing. Guenther's *Institutiones anatomicae* was what we would now call a "cram-book." It appeared first at Basle in 1536, and contains a statement that the promising young Vesalius had demonstrated "for the first time" that the "origins" of the spermatic veins differ from those of the arteries and also from each other on the two sides. It has perhaps not hitherto been noticed that this fact had been recorded at Bologna, the leading Italian school till Vesalius, by Mondino da Luzzi in 1316 and by Giacompo Berengario da Carpi in 1523. The works of both had been reprinted several times by 1536. That Guenther had not heard of this point illustrates, what we know well on other grounds, that the Parisian medical school was almost completely isolated from the Italian schools. Vesalius revised this work of Guenther at the same time as the *Tabulae sex* was issued. "What may have led Vesalius to edit a new edition of Guenther's compendium is not apparent," writes Cushing. We suggest that he regarded it as the best available companion to the *Tabulae*. It would be worth collating the edition revised by Vesalius with the original to see how the changes fit the *Tabulae*.

IV. *The Venesection Epistle*—Basle, 1539—is a member of a long, fierce, and futile controversy as to which side to bleed in pleurisy. Vesalius based his view on the course of the azygos vein and its tributaries and accessories. These we now know to be highly variable. In any event they are irrelevant to such treatment.

V. Contributions to the *Opera* of Galen—Renaissance appetite for ancient medical literature was insatiable. Its *bonne bouche* was a set of huge tomes of the works of Galen. Some twenty editions appeared in the sixteenth century. The most prized were those of the Venetian firm of Giunta. From 1541 onward they included three works revised by Vesalius. The largest was *De anatomica administrationibus*, of which only about half was then known. Rendered into Latin by Guenther and printed at Paris in 1531 and several times since, it formed the staple text for more advanced students at Paris. In revising it Vesalius was on very familiar ground, as he was for the two small tracts which he revised for the same volume. A collation of these three revisions with their originals is necessary before any clear verdict can be given on the Greek scholarship of Vesalius. Indications suggest to us that it was quite superficial.

VI and VII. The *Fabrica* and its companion the *Epitome* must form the main theme of every account of Vesalius. To these works we devoted a leading article on their centenary last year (see our issue of June 26, 1943). It is a puzzle why Vesalius, working at Padua and often visiting Venice, the great neighbouring printing centre, should risk woodblocks and MSS. by sending them across the Alps on a journey of

¹ *A Bio-Bibliography of Andreas Vesalius* By Harvey Cushing. Schuman's New York, 1943; \$15.00.

350 miles, to have his work printed at Basle. We suggest that Basle, being on the Rhine, was convenient for distributing such very heavy books. They could go by water to the north and west of Europe and notably to Germanic lands, where Vesalius wished specially to be read. A German translation of the *Epitome* was in fact made under his own eyes at Basle. Its circumstances have been examined by Prof. Sigerist.² Much has been written on the famous title-page of *Fabrica* and *Epitome*. Cushing exhibits the alleged first, second, and third stages of this remarkable work of art. We confess scepticism as to their genuineness. On the other hand, there can be no doubt that the background of the famous muscle figures has been identified as a landscape near Padua. It must have been drawn on a panoramic scale and the figures afterwards filled in. By studying watermarks Cushing proves that at least one copy survives of a second edition of the *Epitome* printed in 1555 from the same blocks as the first.

VIII. The *Epistle on China-Root*—Basle, 1546—is scientifically the least worthy of the Vesalian works. Its medical outlook is not above that of the day, and is far below that of its greater contemporary exponents, such as Fernel. It reveals, however, some personal relations of Vesalius. For this reason Cushing rightly investigates it thoroughly.

IX. There survive a few *Consilia* of Vesalius. These are replies to questions from professional colleagues concerning specific cases—a conventional literary form of the day. One or two disclose surgical acumen. We could hardly expect less.

X. Second (folio) edition of the *Fabrica*—Basle, 1555, with some not very important improvements on the first edition.

XI. A long *Letter to Fallopius*, printed in 1564 in reply to legitimate criticisms of the *Fabrica*. It weakly stresses verbal rather than real points of difference. Perhaps it was not written for publication.

This is a very poor output for a life centred round the glorious *Fabrica* and *Epitome*. Except for them nothing by Vesalius would be any loss to science. There is the problem. Why was the unique genius of the man fertile only for three or four years? How came it that the greatest exponent of science of his century abandoned his career for a place at court? What sort of character can we descry through the fog of eulogy and legend and sheer hero-worship? To this enquiry, the background for which has been provided by Cushing, three solutions have recently been propounded.³

Dr. Ludwig Edelstein pictures Vesalius as embracing ardently the programme of the "humanist" party. To this he adhered in a deeper sense than in mere respect for classical antiquity. He was a humanist in holding certain aesthetic, historical, and philosophical views characteristic of that great movement and different from those of most of his contemporaries. The points are well made and we concur. But this aspect of Vesalius needs further annotation. First, the "humanist" language of the *Fabrica* is conspicuously unsuited to scientific discourse. Vanity led him to adopt a pseudo-classical style which is neither lucid nor succinct nor beautiful: a thoroughly bad linguistic choice. Secondly, a particular kind of humanism had given him a special bent. From 1531 to 1533, when he was between 17 and 19, he was at the "Collegium trilingue" at Louvain. This three-tongued college and its typical product the "trilinguis homo" had a meaning peculiar to its time and place. Erasmus (1467–1536), embodiment of the humanist spirit, when he coined the term meant one who had gained entry into the spirit of the Latin, Greek, and Hebrew literatures.

The trilingual college at Louvain had been founded a few years earlier by a friend of Erasmus and of Sir Thomas More. Its distinctive ideal left its mark on the young Vesalius though already fading in the place of its birth. Most "humanists" of the day had come to live in a mental atmosphere composed almost entirely of language. Vesalius was far too great to be of these. His sympathies, we suggest, were with the Erasmian school, though he could never have become a trilinguis homo. But his exhibitionist temper led him to overstrain his equipment, so that we see him at once a poor ape of Cicero and a literary dandy flaunting spurious linguistic jewels. His boastfulness bewrayed and betrayed him.

Dr. Zilboorg, an eminent psychiatrist, has sought to display the inner mental life of Vesalius. He regards him as a split and withdrawn personality who, in the end, approached the border-line of insanity. Dr. Zilboorg's theory fits very well the scanty and uncertain data concerning the later years of the great man, but seems to us to fit ill what we know of his earlier years. For we cannot follow Dr. Zilboorg in distinguishing anything sadistic, and still less necrophilic, in the young Vesalius. His boyish interest in the insides of animals seems a healthy inquiry into living mechanism and structure, while his great work cries aloud that it is on *living* anatomy. Nor does Dr. Zilboorg's portrayal fit the well-known portrait of the cocksure, extroverted, sarcastic, vigorous little man that certainly represents the great Paduan teacher. But Dr. Zilboorg renders a service in stressing that, after leaving Padua, Vesalius really did undergo some profound mental change. It seems more likely to us that this took its rise in some intercurrent stress or intoxication. But his immediate reason for abandoning anatomy seems to us no mystery at all. In a worldly sense it was great promotion for a Paduan professor to become physician to the Emperor. No one has yet suggested that Vesalius was unworldly.

Lastly, in a highly erudite, provocative, and witty contribution, Mr. W. M. Ivins of the Metropolitan Museum of Art, New York, would solve the problem of Vesalius by treating him as a Renaissance Mrs. 'Arris. His figure, he suggests, has been created partly by the imagination of scholars and partly by the man's own success in appropriating the work of another. Between 1539 and 1542 "Vesalius according to his own account (1) made two trips to Bologna, where he performed a public anatomy, (2) began and finished editing three of Galen's texts, (3) read Avicenna with Lazarus Hebraeus and compared the text with Hebrew MSS., (4) wrote a careful paraphrase of all ten books of Rhazes, (5) collected the recipes of the classical authors, (6) conceived the ideas for a number of other books . . . (7) carried on his professional task of lecturing and dissecting, and . . . (8) began the text of the *Fabrica*, which he finished in August, 1542." In addition (9) he supervised the artist or artists in the preparation of the 280 woodcuts to the *Fabrica* and *Epitome*.

Since this achievement seems a miracle rather than a *tour de force* of genius, it is well to scrutinize Mr. Ivins's list. The editing of the texts of Galen (2) was a mere trifle involving a few days or perhaps hours. Vesalius surely had ample notes on them from his student days. Two are mere

² *Bulletin of the History of Medicine*, Vol. XIV. Baltimore, 1943.

³ All three appear in the same number of the *Bulletin*.

short tracts. The reading of Avicenna in Hebrew (3) may be dismissed altogether. Vesalius, whatever he may suggest, was quite ignorant of both Hebrew and Arabic. He had hardly grasped even the phonetic value of the letters of these languages. There is no evidence that he ever approached the text of Rhazes (4) with any serious editorial intent. Neither collecting recipes (5) nor conceiving ideas (6) is a time-consuming process. Demonstrations (7) are to most professors what they care to make them. Before the days of preservatives anatomies could never be prolonged. In any event, they fitted the scheme of the *Fabrica*, as did (1) his two visits to Bologna, a short and easy journey. Lecturing (7) would be but trying out the text of the *Fabrica*. As for that text, its obscure and pretentious style is involved and repetitious to the last maddening degree. Easy writing makes hard reading, and the book shows many signs of haste. It might well have been compressed to a quarter of its bulk. It is certain that the greatness of the man was not in the written word. Vesalius is ungenerous and perhaps disingenuous in failing to mention his artist. It is usually assumed, on slender evidence, that Calcar was the man, but there are points against him and we are far from convinced. Mr. Ivins seems to overstress the difficulties of an anatomically untrained draughtsman in representing structural detail under skilled guidance. At the same time he underestimates the draughtsmanship of Vesalius himself, of which we have some means of judging. To Calcar Mr. Ivins gives most of the credit of the *Fabrica*. But of Calcar we know even less than of Vesalius.

Seyde Plato, "Ye, sir, and is it thus?"

This is ignotum per ignotius."

(Chaucer, *Canon Yeoman's Tale*, lines 1456-7.)

No, there was certainly a human and a very great Vesalius. He was clearly not a man of many friends. He had some repellent traits; in his later years he was secretive and eccentric and may even have been semi-insane. He was certainly vain and boastful, and as a writer had most of the faults of the humanists and few of their virtues. His worst feature perhaps came out in his ambition, for he abandoned, as have many, a great scientific career for the meanly reflected glamour of a life at court. But there is every reason to believe that he was, in every material sense, the creator of the *Fabrica* and the *Epitome*. He was therefore the greatest of modern medical men. But much more patient research is needed before we can discern clearly the essential elements of his character.

MEDICINE AND POLITICS

The present lull in medical politics will give many the much-needed opportunity to reflect upon events before the Annual Representative Meeting at the beginning of December. The Press generally, and the *Times* in particular, have given generous space to discussion on the numerous controversial points that have come to the fore since the publication of the White Paper. The political

axe-grinders have tried to prejudice the issue by suggesting that opinions held by the medical profession and the B.M.A. have hardened into reactionary opposition. The medical profession has, indeed, reacted to the attacks made upon it, and to the misrepresentations made by those who want to use medicine to further their political aims. As Lord Dawson in his admirably phrased and wise letter in the *Times* of Sept. 16 observed, "There is a school of political thought desirous of seizing this opportunity for furthering its particular ideology of socialization, which would mean for medicine a whole-time service as part of the Civil Service and its members one and all paid by salary." Lord Dawson shows how fully aware he is of the activity of "extraneous forces" when he goes on to say: "The intent and impact of this influence, in the face of the Government's repeated assurance that they have no such intentions, *undermine confidence and render difficult the efforts of those on both sides who are seeking the way of agreement*" (our italics). And he lends force to his own observations by quoting the following from a recent speech by the Prime Minister: "Ideology too often presents itself as undue regimentation of ideas and may be very likely incompatible with freedom." These views have been consistently expressed by the *Journal* and reiterated in several leading articles over the past two years. Doctors up and down the country have become more and more disquieted by the attempt on the part of "ideologists" to exploit the situation created by the war with the aim of imposing their doctrinaire political conceptions upon a profession which is perhaps ill acquainted with the astuteness of political propagandists. That doctors have "reacted" to this situation is a welcome sign. It is, however, false to interpret this "reaction" either as a refusal to co-operate with the Government or as a sign of ignoring the need for medical reforms. As Lord Dawson points out once more, this is contrary to the facts. "There is," he states, "little dispute over objectives, but there are differences about methods of administration on which accommodation is being sought." He says flatly that "advisory committees standing alone outside the executive body are futile," and that "the profession insists on a substantial share in the planning and administration of the proposed service at every level." One thing this war has taught us, he acutely observes, is "that national enterprise must be guided by expert knowledge." "Can it be pretended," he asks, "that local authorities know anything about medicine?"; and suggests a way out of this obvious dilemma by proposing that "medical and other skilled persons" should serve on local bodies alongside the elected representatives of the people. He emphasizes that the profession does not seek to dominate but to share the work of planning and execution. Turning to central administration, he asserts that the profession has no wish to wrest from the Minister and Parliament final responsibility for the proposed service, but he is equally clear that the profession "will not accept subjugation by the service" (our italics). The fear of doctors that civil servants want to be the "masters" and not the "obedient servants" is by no means groundless. Lord Dawson has put an unerring finger on the central weakness of the planner's anatomy.

SODI. BIC.

The dyspeptic is always with us, and sodium bicarbonate alone or in company is in many instances his sheet anchor. This drug, however, has fallen on evil days among the pharmacologists. The usual teaching is that after a brief period of neutralization hydrochloric acid appears in increased amount in the gastric juice. The mechanism underlying this "rebound" secretion has not been satisfactorily explained. Adams and his colleagues¹ mention the possibility that the increase in hydrochloric acid concentration may be due to more rapid emptying of the stomach, with consequent decrease in the dilution of the high acid secretion of the oxyntic cells. In an attempt to throw light on this problem they made use of the Cope gastric pouch in dogs and thus obtained an accessory stomach with nerve supply intact, and so situated as to act as its own collection vessel. The sole drawback to this technique was the necessity to use an antacid to prevent peptic ulceration: for this purpose measured amounts of aluminium hydroxide were employed with advantage. By this means it was possible to measure gastric secretion continuously. Control investigations showed that under constant conditions the day-to-day variations were very slight. The effect of sodium bicarbonate was determined by the intragastric administration of 50 c.cm. of 1.5 or 2% solution of sodium bicarbonate or by placing a 4% solution directly into the pouch. The 24-hour volume and total chloride were unchanged, but greater amounts appeared directly after the administration of the alkali. The secretion of free acid also showed an immediate increase which was only partly compensated by the later decrease, so that the amount secreted during the 24 hours was significantly higher than in the control period. The rebound increase in free acid which has been noted in the human subject is therefore in part due to a more rapid secretion produced by the bicarbonate, and the acid concentration is still further enhanced by more rapid emptying of the stomach. The actual mechanism producing these changes is still obscure, but the fact that the effects are the same whether alkali is put into the stomach or into the pouch suggests that it is more than a mere local effect on the secreting cells. If necessary this work confirms still further the view that continued administration of sodium bicarbonate is deleterious to patients with peptic ulceration, because for a long period after each ingestion of the alkali the ulcerated area is exposed to higher concentrations of free acid.

CHAIR OF CHILD HEALTH IN LONDON

With Lord Nuffield's full approval the Trustees of the Nuffield Foundation have decided to allocate £10,000 annum for a period of 10 years for a Chair of Child Health in the University of London. The offer of the Trustees has been gratefully accepted by the University. The financial assistance provided by the Foundation will enable a postgraduate Institute to be created for teaching and research on all aspects of child health. It is proposed that the Institute should be associated with the Hospital for Sick Children, Great Ormond Street, and the Obstetric Department of the British Postgraduate Medical School at the Hammersmith (L.C.C.) Hospital, London. Lord Nuffield and the Trustees of his Foundation believe that the promotion of child health must have a prominent place in the organization of the future health services of the country. They appreciate that the development of research and training in this sphere of health service requires new and enlarged facilities. The provision of academic centres for the teaching of child health is

already being undertaken in several provincial universities, and the Nuffield Provincial Hospitals Trust has, within the last three years, made a substantial contribution to the University of Durham to assist in the creation of a Chair of Child Health at King's College, Newcastle-upon-Tyne. The munificent grant the Nuffield Foundation is now making has been influenced by the desire of the Trustees that the exceptional resources of the University of London for medical postgraduate education and research may be developed in a manner which will make the new Institute of Child Health worthy of the capital city of the country and the Empire.

BIOPSY IN SCHIZOPHRENIA

It is notoriously difficult to protect after death tissues removed from the body from post-mortem changes which complicate and obscure the histological picture. Furthermore, there will often have been changes during the terminal illness to add to the difficulties of interpretation. The pathologist is, in effect, forced to rely on his wide experience of control material, in the form of tissues believed to have been healthy, for a comparison on which to base his judgment. It might be thought that the whole difficulty could be evaded by the use of biopsy material. Tissues removed from the living body and fixed with great speed might be expected to be fairly free from these unwanted adventitious changes. There then arises, however, a second source of difficulty. The new method introduces cellular changes of its own, and the pathologist, as a rule, has by no means the same wealth of experience of control material to guide him. Bioptic examination of the brain is of much interest and value. For some purposes—e.g., studies on the oligodendroglia—it is essential, as agonal changes lead to swelling of these cells.¹ In neurosurgical practice biopsy investigations are of the greatest value in connexion with the treatment of tumours. Nevertheless the artefacts which can be produced in these small pieces of tissue, and which are then liable to misinterpretation as pathological findings, were well known to Nissl,² and have been made the subject of an experimental study by Rose.³ Nissl's chronic change of cell sclerosis may be entirely due to the effects of fixation.

Kirschbaum and Heilbrunn⁴ have recently reported an investigation by biopsy of the brains of schizophrenic patients and experimental animals. Fully aware of the dangers referred to, they took precautions by procuring animal controls. It is not clear that this control work was on an entirely adequate scale. Their human material was obtained from physically healthy schizophrenic patients during the operation of prefrontal lobotomy. The cases were chronic, with an average duration of illness of over fourteen years, so that the changes that might be looked for with a fresh and florid psychosis could not be expected. The authors found degenerative changes of the ganglion cells and progressive and regressive reactions of the glia and blood vessels, such as are commonly seen in cases of chronic intoxications and metabolic disorders. Their experimental controls indicated that these changes could not be attributed to the ether narcosis employed. The changes they describe are, however, slender, in some ways obscure, and nowhere far from the normal or accidental range. But this method of attack on the aetiology and pathogenesis of schizophrenia is of interest and holds some promise. It is to be thought of in connexion with other lines of attack—e.g., physiological and electro-encephalographic. Schizophrenia is commonly looked on as a

progressive disease, or as a "process" taking place in the brain; but the occasional reversibility of signs and symptoms even in chronic and demented cases suggests that gross structural changes are unlikely. It is, perhaps, more probable that the final clue will be found in a deviation of brain metabolism, which once started tends to perpetuate itself in a vicious circle.

VITAMIN C AND CALCIFICATION

It is well established that adequate amounts of vitamin C are necessary for the laying down of the organic matrix of bone, but until recently it was not known that the vitamin is necessary for the production of bone salt. Thus Wolbach and Bessey¹ have stated that vitamin C plays no part in the process of calcification, and Boyle, Bessey, and Howe² reported that calcification continues in the teeth of guinea-pigs even when they have been a long time on a scorbutic diet. Bourne³ of Oxford has recently described experiments the results of which suggest that the deposition of bone salt in normal and regenerating bone is retarded in scorbutic animals, but not in the bone of animals receiving adequate amounts of vitamin C. In the normal animal it would seem that so long as there is sufficient vitamin C to produce the organic matrix of bone the matrix will be calcified. The apparent failure of certain bones to deposit bone salt in scurvy may be due to the fact that there is no matrix on which the calcium may be deposited. It will be recalled that the earlier workers on bone formation and vitamin-C deficiency used lemon and orange juices as sources of vitamin C. Bourne has shown that it is actually vitamin C and not associated substances, such as vitamin P or citric acid, that is responsible for the laying down of the bone matrix and the deposition of calcium salts. Both vitamin P and citrates were devoid of any effect. He suggests that the function of vitamin C in bone formation is to facilitate the production not only of bone matrix but of bone matrix impregnated with phosphatase. The association of vitamin C with phosphatase activity in bone has been confirmed by Schwachman and Gould,⁴ who have shown that there is a reduction of both bone and serum phosphatase in scurvy. There is no evidence at the moment that vitamin C is the coenzyme of the phosphatase in calcification. As Bourne points out, the apparent reduction of phosphatase activity in scurvy is probably due to a reduction in the amount of bone matrix produced, rather than to a reduction in phosphatase *per se*. Any matrix formed at all in vitamin-C deficiency will probably be as heavily calcified as the matrix formed in normal animals.

SICKNESS ABSENCE IN INDUSTRY

The importance of recording the sickness absence of their workers is recognized by many if not by most large industrial organizations, for such records enable them to determine their effective labour strength and to gain knowledge of the influence of various conditions of work on the health of those employed. Unfortunately the methods adopted by different firms lack uniformity, so it is often impossible to compare the sickness rates of the firms by valid statistical methods. A uniform method of calculating sickness rates is therefore an outstanding need, and a committee of the Industrial Health Research Board has now issued a preliminary report⁵ with the endeavour, in the words of the report, of making "a complicated and, in some respects, a controversial subject as simple as possible."

The system of record-keeping recommended has already been put to the test by several large firms, and the cost of the clerical help required appears to work out at less than 4s. per worker per annum. The cards used for the records show the certified and uncertified sickness absence, absence due to accidents, and absences due to other causes, for a two-year period. The disease groups into which the illnesses are classified are seven in number, based on a provisional classification used by the Medical Research Council. Illustrative forms are given by the committee for classifying the causes of sickness, and for the group analysis of absence due to sickness and accidents.

Related, in some of its aspects, to the Health Board's report on sickness absence is the memorandum by the Factory Department of the Ministry of Labour and National Service on medical supervision in factories.⁶ This memorandum summarizes the principal duties of a works medical officer, including the examination of the workers under certain conditions, and their interview, or examination, on return to work after injury or illness. It maintains that the works medical officer will have an essential part to play in any schemes for the reconditioning and resettlement of disabled persons in industry, for he has first-hand knowledge of the processes carried out in the factories under his supervision, and of the physical requirements necessary. Thus it is essential for him to make himself acquainted with all the processes in the factory, whereby he may be enabled to assess the relative liability to sickness and injury from each process concerned. Arrangements for first aid and the personnel who carry it out are discussed, the employment of a State-registered nurse (or nurses) being strongly recommended. Medical records of each worker should be kept; these must be under the care of the medical officer, and some attempt at uniformity should be made for purposes of comparison.

A NEW APPROACH TO GOUT

It is well known that chickens, as do other birds, excrete much nitrogen in the form of urates. Apparently if chickens are fed not on the usual grain diet, but on a meat diet, the plasma uric acid rises and deposits of uric acid are formed exactly like the tophi of human gout. Oppenheimer and Kunkel⁷ have fed chickens in this way, observing the plasma uric acid to rise from 3 or 4 mg. per 100 c.cm. plasma to 15-17 mg. and tophi to appear in 8 weeks. They have obtained from pig's liver a preparation of uricase which, after purification, they inject into the chickens intramuscularly. This enzyme causes a lowering of plasma uric acid, so that from 50 to 80% of the uric acid disappears in one hour, the effect lasting for varying periods up to 32 hours. Oppenheimer and Kunkel also found that daily injections of uricase kept the plasma uric acid well below that of control chickens over periods of two months. These observations may provide a method of treating gout in human subjects. At present it is not possible because of the large amounts of uricase needed, and it will be necessary to concentrate the uricase considerably before it can be used. The authors have, however, injected into one gouty subject as much as 17 c.cm. of their purest material, and though it did the patient no good they are pleased that it did him no harm. The solution of uricase can be sterilized by filtration.

Lord Dawson of Penn has entered hospital for an operation. He expects to be back at work in seven or eight weeks.

MINERS' PHTHISIS BUREAU OF S. AFRICA

The report of the Miners' Phthisis Medical Bureau, Union of South Africa, for the three years ended July 31, 1941, records a considerable decrease in the number of initial examinations of miners, partly due to the intensive Army recruiting which followed the German invasion of the Low Countries. In other respects, except for the absence of some members of the staff on military service, the work of the Bureau has not been appreciably affected by the war, for it has been the policy of the Union Government that there should be no curtailment of the activities of the gold-mining industry. With the institution of a more intensive system of seeking out possible cases of pulmonary tuberculosis or of silicosis the number of examinations of native labourers has increased. The Bureau is now housed in a new building specially designed for the purpose. Within it are stored about one million x-ray films and the clinical and radiographic records of over 177,000 European and 48,000 native labourers.

From an analysis of a large number of fatal cases of primary cancer of the lung in Europeans it would appear that this disease is no more prevalent among silicotic than among non-silicotic miners or even men working above ground. The Bureau investigated the incidence of silicosis in an iron ore mine at Thabazimbi in the Rustenburg district. In this mine hand-held machine drills are employed, and silica, although present in the ore only in a very small percentage, is reduced by the drilling to extremely fine particles. Examination of a number of European and native workers from this mine showed pathological changes in the lung similar to those produced in a generalized simple silicosis; but in the early stages the lesions were finer than those observed in similar cases among Witwatersrand gold miners. Post-mortem examinations of the lungs of two workers, one European and one native, from the mine shed some light on the pathological condition produced. Earlier radiographs had shown "generalized small mottling" in both cases. The native died later of lobar pneumonia, and the lungs showed widespread, haematite pigmentation but no fibrosis. The European died from right-sided cardiac failure. In his case the pigmentation was accompanied by fibrotic changes, and microscopical examination confirmed the presence of a marked degree of sidero-silicosis. Since the enforcement of regulations to reduce the danger from dust in this mine no further serious cases have been seen, and the examination of a cat and several guinea-pigs, which were kept at the working faces for more than a year, revealed only slight deposits of haematite dust and no sign of any fibrosis.

RAPID SURVEYS OF AIR POLLUTION

Atmospheric pollution, which is the chief cause of the difference between the air in towns and the fresh air of the countryside, may in general be said to consist of (1) relatively coarse solid matter, such as ash or grit, which is usually deposited fairly quickly near to its place of origin; (2) fine solid matter, such as smoke, which remains suspended in the air for a relatively long time; and (3) gases, such as sulphur dioxide emitted from domestic or industrial chimneys, engines, etc. It is relatively simple to record the quantities of each of these forms of pollution, and from the records over a period of time to determine whether the pollution in a town is changing in its quality or quantity. It is becoming increasingly important, however, to be able to make more rapid estimates of the distribution of pollution in a particular locality at any given time, because although the normal type of recording apparatus is very simple it cannot usually provide reliable information quickly. Where such information is wanted at short notice—e.g., as part of consideration of post-war industrial or housing plans—it may be obtained with sufficient accuracy for the immediate purpose by the methods described in a memorandum drawn up by the Atmospheric Pollution Research Committee of the Department of Scientific and Industrial Research, Teddington, Middlesex. The memorandum describes rapid methods of measuring (1) deposited solid matter, (2) suspended solid matter, and (3) SO_2 in the atmosphere. Copies of it, and advice on the conduct of such surveys, may be had from the secretary of the committee.

R. J. Needles and P. D. Gilbert (*Arch. intern. Med.*, 1944, 23, 113), who record their observations on 125 cases of atypical pneumonia with only one death, maintain that there is an increasing number of cases of an interstitial pneumonitis associated with capillary bronchitis, of undetermined cause or little tendency to excessive mortality. Evidence shows that the cause is to be found in the group of virus-Rickettsia agents. The symptoms and pathological changes strikingly resemble those present in some cases of influenzal pneumonia. Treatment must remain symptomatic until new effective therapeutic agents are discovered.

Correspondence

Pituitary Cachexia

SIR.—The recent paper by Hemphill and Reiss (Aug. 12, p. 211) is of special interest to me, and as the theoretical basis of their treatment is open to misinterpretation I wish to discuss their observations.

Pituitary cachexia (Simmonds's disease) is generally understood to signify the clinical consequence of some organic lesion of the anterior lobe. It is a term which is in less use now than hitherto, as recent observers have stressed that cachexia is not a necessary or even characteristic feature of the disease (Sheehan, 1938). Hypopituitarism (or the more unwieldy term "pan-anterior hypopituitarism") is now more commonly used. Hypopituitarism of a severe degree is invariably due to an organic lesion (primary hypopituitarism), while milder manifestations frequently occur in many wasting cachexias (secondary hypopituitarism). Stephens (1941) has fully discussed the evidence to support this latter contention in the case of anorexia nervosa, but the arguments apply just as well in diseases of malabsorption—e.g., small-bowel diseases—or diseases of metabolism, such as chronic, insufficiently treated diabetes mellitus. Under such conditions, it would seem as if the body conserved itself by stopping growth and menstruation, and lowering O_2 consumption. Spontaneous energy is the last to diminish, and probably depends largely on the efficiency of the adrenal cortex. It is as if the pituitary hormones are progressively inhibited in reverse order of their immediate importance to the survival of the individual.

This general theory of selective pituitary secretion has been advanced in a preliminary communication by the author in 1943. Since then a reasonable amount of clinical data has been accumulated to support it. Some evidence suggests that if the cachexia is secondary to a subacute or chronic infection—e.g., tuberculosis—the pituitary reacts by inhibiting growth and gonadotrophic hormones and increasing the secretion of at least corticotrophic hormone. The idea of the pituitary switching from the less essential to the more essential hormones in time of stress was originally put forward by Selye (1936) from studies in rats. The application of these views to clinical endocrinology would tend to avoid confusion and make more explicable to students some of the commonest types of endocrine disturbances, such as amenorrhoea or retarded growth and sexual development secondary to some not too obvious disease elsewhere. It would also explain some of the vagaries of diabetes mellitus.

Presumably, therefore, Hemphill and Reiss have been dealing with an example of mild hypopituitarism secondary to a distaste for food coupled with mental symptoms. The anorexia caused the cachexia, and hypopituitarism followed—just as it would if the patient had carcinoma of the oesophagus. In fact, their patient started to get well when the appetite returned. It does not follow, as one might be tempted to deduce, that corticotrophic hormone is indicated in any wasting condition of obscure origin even with biochemical evidence of hypopituitarism. I mean in no way to minimize the importance of their observation in the particular type of patient they reported. So far as I am aware the accepted basis of treatment in such emaciated mental cases is intensive and even forced feeding to improve their general health. Hemphill and Reiss may well have found a more superior therapy in corticotrophic hormone, and it is not improbable that adrenal cortical extracts, with salt and D.O.C.A., would have achieved a similar success. Possibly this patient was in a vicious circle in which the loss of appetite caused a hypopituitarism which in turn lowered the general health and further exaggerated her mental condition with its associated anorexia. The fact that their patient continued to improve long after the injections were stopped substantiates the view of a temporary inhibition of the anterior-lobe secretion (secondary hypopituitarism) rather than a true "pituitary cachexia."

I have recently observed the response to corticotrophic hormone in a patient suffering from typical Simmonds's disease (due to post-partum necrosis). After seven days the patient noticed a general sense of well-being with improved appetite and diminished asthenia. By twenty-seven days the weight had increased 5 lb. (to 108 lb.) and the B.P. had increased from 95/60 to 100/70. Notwithstanding injections for over three weeks there was no further improvement. The insulin tolerance was not appreciably improved at any stage of the treatment. The patient deteriorated in later courses of injections,

suggesting the formation of antihormone, although it is possible the extract had lost some of its activity. The response, therefore, was entirely different, as one would expect, from that observed by Hemphill and Reiss.—I am, etc.,

Intramuscular Quinine

SIR.—Sir Philp Manson-Bahr, in the course of his interesting letter on war malaria in the *Journal* for Sept. 9, refers to the efficiency of intramuscular injections of quinine. From an experience of 20 years in East Africa, during which I have given some thousands of injections, I can heartily endorse Sir Philp's observations. Intramuscular injections are particularly useful in cases of pregnancy, and where incessant vomiting is a bar to oral administration. There are two points to which I wish to attract attention. First, the site of the injection should be thoroughly and deeply massaged for a full minute to disperse the acid and to dilute it with the body fluids. I have never had a case of sloughing or paralysis, but have seen several where this ritual has not been performed. The second point is that a mineral acid would not seem to be the best vehicle for an intramuscular injection. I would suggest lactate of quinine, in which the acid is a normal product of muscle metabolism, should be more suitable theoretically. Unfortunately I can find no reference to its solubility, though other hydroxy acids, such as tartaric, produce a soluble salt. The point is worthy of further investigation, I think.—I am, etc.,

The Metric System in Medicine

SIR.—Prof. W. C. W. Nixon's plea¹ for the exclusive use of the metric system in medicine comes at a singularly opportune moment: (i) there is every indication that there will be extensive changes in medical organization and practice in other directions; (ii) limitation of supplies of drugs has altered prescribing habits, and tended to favour drugs—e.g., sulphonamides—which are dispensed metrically; (iii) the many men who will be returning from the Services to civilian practice should find it relatively easy, among the much greater adjustments that they will have to make, to assimilate this reform. It seems improbable that such a favourable combination of circumstances will recur.

While there may be strong arguments against the change to the metric system in engineering, the case for retaining imperial and apothecaries' units in medicine is surely very feeble. It has been argued that the older systems provide more convenient doses, but even this dubious advantage is fast disappearing with the increasing number of metrically dosed synthetic drugs. Further, the arbitrary "t.d.s., p.c." convention of dosage tends to be replaced by a rational schedule designed to bring about the necessary concentration of the drug in the body fluids for the necessary time. It is inconceivable that concentrations of drugs in the body would ever be measured in terms of grains per pint, and with changing conceptions of pharmacotherapy the position has almost been reached at which the system of mensuration used for a drug, with the exception of a few active principles of plants and inorganic compounds, may be regarded as an indicator of its value.

There is no point in pleading for the use of the metric system by medical scientists, because they have adopted it without question. It is only in medical and pharmaceutical practice that the older units survive as worthless anachronisms. Quite apart from the relative merits of the different measures, the existence of a dual system of mensuration in medicine is an intolerable anomaly. It is not uncommon for prescriptions to contain a blend of imperial and metric units, or, as Stiehl² has pointed out, for ampoules to be dispensed according to metric volume and imperial weight—e.g., "ephedrinae sulphas, 3/4 gr. in 1 c.c." Stiehl has also drawn attention to another absurdity: "Year after year, when medical students reach the clinical subjects, they abandon the most satisfactory system of weights and measures ever devised and adopt

either the imperial or apothecaries' system. . . . They do even more than this. They adopt Roman numerals in preference to Arabic and signs in preference to words." What is the value of these signs? They are of such antiquity that the date of their introduction and their original significance are matters for dispute,³ and they have the serious practical disadvantage that their use is a notorious source of prescribing errors. They, and the use of grains, minims, and drachms, belong to a vanished age which was entertainingly described by Sir Clifford Allbutt⁴: "When I began practice it was customary at every consultation to prepare a writing-table, pens, and ink for 'the prescription.' This script, even in my young days, was of formidable composition, a drug for every symptom, and a few more for the pool, it was solemnly set forth, and signed by two or more physicians. by the patient's friends this was understood, if but long enough, to be the organ of his restoration. No occasion was left for modification according to circumstances, or the various phases of the disorder; to it the doctor in attendance was to be as submissive as the patient to whom it was scrupulously administered."

Although prescription writing is no longer an "art," and consultations are less of a pantomime, the old measures and signs remain as relics of obscurantism, and of ignorance masked by pomposity and pretence. If any should regard the proposal to abandon imperial and apothecaries' measures in medicine as premature, they will be relieved to know that, 118 years ago, Andrew Duncan senior pointed out,⁵ at the respectable age of 82, that their use was "attended with many inconveniences," and suggested that "without adopting the new French weights" we should imitate them by using decimal multiples of the grain. Duncan did not give any reasons against the metric system. Possibly, as a recent product of the French Revolution, it was not considered acceptable. The *Lancet*⁶ approved Duncan's suggestion in principle, but recommended that "instead of adopting an alteration of weights for pharmacy, as proposed in this letter, it would be more advisable to wait a little, until the Government shall ordain the decimal proportions of weights and measures to be generally used, which we anticipate to see done in a few years." Although other countries, one after another, have adopted the metric system, and its claims in medicine have often been reiterated, the *Lancet's* prophecy remains unfulfilled after nearly a century and a quarter.

Some further reasons against adherence to imperial and apothecaries' weights and measures may be summarized as follows: (i) Their use is a formidable barrier to the understanding of British medical literature by medical men of most other countries. (ii) They are a source of ambiguities—for example, "ounce" is often used in such a context as to make it difficult to determine whether solid or fluid measure is intended. (iii) A dual mensuration in medicine is not only irrational but dangerous—"gr." means "gramme" in Continental and "grain" in British medical literature, and the confusion of these two units has, even in this country, caused many accidents. (iv) The relation between imperial and apothecaries' units is confusing. (v) The range of units available is inadequate for present needs. (vi) Calculations are laborious. (vii) There is no simple relation between linear, solid, and fluid units.

In December, 1943, the Council on Pharmacy and Chemistry of the American Medical Association gave⁷ its reasons for the exclusive adoption of metric quantities and dosages in all its publications, and concluded "The universal adoption of the metric system would be a manifestation of rationality and of interprofessional and international co-operation of high practical utility." In this country the Pharmaceutical Society has recently said⁸ that "there is no doubt that the pharmacist finds the metric system more easy, convenient, and, what is as important, nearly fool-proof."

There may be some who think that it would be difficult to abandon the old habits of mensuration. The experience of working before the war for 18 months in a country in which the metric system was exclusively employed convinced me that the change could be made very easily, and that the advantages of working metrically not only in medicine but in the kitchen, the nursery, and the improvised dark-room of the amateur photographer, were considerable.

In the light of these considerations, there would seem to be no valid reason for continuing to make ourselves unintelligible to our medical colleagues in other parts of the world. I

suggest that it would be fitting for the *Journal* to take a lead in this matter by asking all contributors to use metric units or to give metric equivalents to other units in parentheses.—I am, etc.,

N. HOWARD JONES.

SIR,—Many readers will agree with Prof. W. C. W. Nixon (Sept. 2, p. 320) that the time is opportune for the adoption of the metric system in medicine. This development—which is ultimately inevitable—is being allowed to take place gradually, but haphazardly, and is a potential source of much confusion and error which could be avoided or passed over quickly by a deliberate change from one system to the other. I agree with your correspondent that the best opportunity likely to occur for many years will present itself in the near future.

If the present rate of medical progress is maintained, doctors will soon find themselves in a position to appreciate that a clear decision is necessary. In medical research, and in laboratories providing routine services for the medical profession, the metric system is established. Whenever scientific methods are applied in medicine the metric system is employed as a matter of course. This will affect the general practitioner; as research becomes more closely integrated with clinical practice, and the use of laboratory facilities is extended, he will find himself forced to adopt the metric system also, or be prepared to perform a series of mental acrobatics at increasingly frequent intervals. Already the metric system is used where applicable for reporting the results of laboratory tests, and I have heard no complaint on that score. Blood sugar, for example, is given as so many milligrammes per 100 c.cm. Toxicity is stated in terms of grammes per kilogramme body weight, and, logically, dosage is sometimes computed on a similar basis; a little thought will bring to mind several similar instances. Doctors are familiar with the use of the metric system in parenteral therapy, although they persist in using solutions containing so many grains per c.cm. The vitamins, minerals, and the newer therapeutic preparations, such as the sulphonamides, the synthetic oestrogens, local anaesthetics, pethidine, hexobarbitone, mepacrine, and others, are being prescribed in metric doses without—so far as I am aware—any great strain in the consulting room. This tendency is obviously going to become more extensive, with at least one unfortunate consequence. I have already seen prescriptions in which the dose of one ingredient was stated metrically while the others were according to the apothecary system. This is not only ridiculous, it is potentially dangerous. It is not always easy to determine whether grains or grammes are intended, and if these expressions in their abbreviated illegible forms are to appear in one prescription trouble must be expected. A deliberate adoption of the metric system might not eliminate all possibility of confusion and error, but it would limit their duration to as short a time as possible, and, I forecast, would not cause very much more disturbance than the introduction of a new edition of the *B.P.* or the *National Formulary*. Doctors may take a second or two longer to write a prescription, but if the result is greater clarity who can object?—I am, etc.,

Centford Middlesex

J. THOS. MARSH.

Pentothal Anaesthesia

SIR,—We have been looking forward each week recently to the *British Medical Journal* with much more interest than usual, in order to read the latest notions about anaesthetics, especially pentothal. In this department pentothal has been almost exclusively used since its introduction, as being most convenient and the safest anaesthetic for radium insertions and minor operations; and, since no fewer than 100 cases per annum are done, one of us at least (R. R. M.) can lay claim to considerable experience of it.

The cases represented by those requiring radium insertions form, in our opinion, the worst group of anaesthetic risks in the surgical field. Few patients are under 50 years of age, most are over 60, and many are between 70 and 80. The vast majority have arteriosclerosis to a more or less marked degree, and many have demonstrably poor myocardial function. Not a few are obviously toxic from their neoplastic process. Yet we have not one case to record of an anaesthetic death, either on the table or in bed after operation. Only on rare occasions, when an inexperienced anaesthetist has allowed partial asphyxia to occur, has operation had to be suspended. We have never

seen vomiting on the table; it has happened—mildly only—in a very few cases during the stage of recovery. Laryngeal spasm has been met with once or twice, but only when the patient has been allowed to become too lightly anaesthetized: when it does occur it proves most intractable, even if the anaesthetic is then pushed. Bronchopneumonia, which is very frequent in radium needling of the mouth region under inhalational anaesthesia, has been practically abolished by the routine use of pentothal.

Briefly, our routine technique is as follows:

1. Premedication: morph. sulph. gr. 1/4 and atropine sulph. gr. 1/100. This appears to lessen the requirements of pentothal.

2. 1 g. of pentothal in 20 c.cm. is used. More than this has never been necessary for our purposes, the average length of anaesthesia in our cases being 15 to 20 minutes. Long intravenous needles with a short bevel are used. The largest antecubital vein (variable in position) is chosen. The skin is wiped with spirit, an elastic bandage tourniquet applied, and the patient told to open and close the hand while the surgeon is scrubbing; ample time is thus given for the veins to become prominent.

3. When the vein is entered, the tourniquet is removed and the patient asked to count out loud. Induction is rapid—at the rate of approximately 1 c.cm. every two seconds. The counting almost invariably stops at about "16." Another 3 c.cm. is then given and administration is stopped. The average amount required for induction is 8 to 9 c.cm.

4. Further pentothal is given, 1 c.cm. at a time, as indicated. We find that when the patient is fully induced, as described above, the breathing is inaudible and one has to watch closely to perceive respiratory movement. The criterion adopted is that when breathing becomes audible more is required. We find that if this rule is not followed, face-twitching or slight leg movements soon begin. During the whole anaesthesia positive pressure is kept on the syringe plunger to prevent blood reflux and clotting within the needles. So far this accident has not occurred.

The main difficulty experienced in all pentothal cases is the inveterate tendency of the tongue to become completely flaccid and fall back. Probably the tendency is not greater than in ordinary anaesthesia, but it assumes greater prominence as the anaesthetist is away from the head and unable to exert manual control of the jaw. We have now adopted the practice of employing tongue forceps almost as a routine, handing them over to an assistant. A small point of technique, which we find makes a vital difference in a busy theatre where two or three pentothal cases are following in quick succession, is as follows. The needles, freshly sharpened before each theatre day, arrive in the theatre in brass trays: they remain in these during sterilization, and are removed only immediately before use. Blunting by hitting against dishes, etc., is thus avoided. This rule about needles is strictly enforced. Pentothal has accidentally been spilled into the tissues on a few occasions, but not once recently has there been any local reaction. For some time we ordered hot fomentations on return to bed in such cases, but have given these up without ill effects. Some months ago reactions sometimes occurred after spilling, and in two or three cases caused sloughing, which healed without difficulty. It is thought that some abnormality in materials may have accounted for this.

In conclusion, our judgment is that pentothal is not only ideal for the special purpose of a radium therapy department but has also proved very safe in a series of unselected cases, including many bad risks. It appears to us that any patient who is clinically likely to survive more than a month is a safe risk for pentothal. We now give it without hesitation to patients in the seventh and eighth decades; to those with cardiac irregularities, often gross; and to those showing obvious signs of toxæmia. Many of the anaesthetics in our series have been given by inexperienced house-surgeons under guidance from the surgeon. On other occasions more senior residents have acted as anaesthetists. Probably not more than 10 inductions have been given by specialist anaesthetists. The last 50 or so cases have been anaesthetized by one of us (D. M. M.) without the surgeon on any occasion requiring to cease operation or to give any attention to the patient so far as the anaesthesia was concerned.—We are, etc.,

ROBERT R. MORRISON, M.B., D.M.R.E.,
Medical Officer in Charge, Radiotherapy
Department, Glasgow Royal Infirmary.

DONALD M. MACKAY, M.B.,
Ex-Resident House-surgeon,
Glasgow Royal Infirmary.

Pentothal in Nasopharyngeal Operations

SIR—There has been so much oral discuss on and printed correspondence about Dr E R Dingles and Dr F W Roberts's letters that appeared in your *Journal* of July 29 and my letter of July 15 that I should like to state that I agree with Dr Roberts's first point.

If I were an anaesthetist I should refuse to give sodium pentothal unless the operator packed off the nasopharynx with gauze and had an aspirating motor beside him. The anaesthetists who anaesthetize my patients insert a metal airway into the mouth during the induction of anaesthesia, and then, when the patient is asleep, they insert a rubber airway which passes over the back of the tongue, and through this a catheter is passed for the administration of oxygen. Before I begin operating on the nose I pass a piece of gauze with tape attached into each nostril, passing the gauze into the nasopharynx and letting the tape lie on the floor of the nose to facilitate its removal. Besides this I have a hand electric suction motor to suck blood from the pharynx in case the pharyngeal dam is ineffective.

In a tonsil dissection, after the patient is under the sodium pentothal I introduce a Boyle Davis gag, extending the patient's head by placing two pillows under his shoulders. This position allows the blood to flow into the nasopharynx, from which it can be aspirated by the suction motor. If general anaesthesia is necessary following on the sodium pentothal a Magill tube is introduced, and, in future, when a Magill tube is used I would recommend that Rowbotham's balloon be used (*Lancet*, July 1, 1944), which will certainly prevent any aspiration of blood into the bronchi.

As regards Dr Roberts's criticism on the use of picrotoxin, in future I shall accept his criticism and use leptazol, which is as active as picrotoxin if given in larger doses than picrotoxin, and is certainly more potent than coramine.

As regards the dose of morphine, it is true that I have used 1/4 gr doses, but on account of recent criticism I have cut it down to 1/6—giving morphine 1/6, scopolamine 1/200, and atropine 1/100.

As regards Dr Dingle's letter, he states he gained the impression that the death of my patient was considered to be due to primary cardiac failure. That does not mean that Dr Dingle himself believed that death was due to that cause—merely a piece of politeness showered on me—for he has told me in conversation that he knows that sodium pentothal never produces primary cardiac failure, but that it always first produces respiratory failure, and it is for this reason that he has planned his treatment.

I hope now that young anaesthetists will be armed with rules, and will have the courage to enforce them—i.e., not operating without oxygen and an aspirator, having proper packing off of the nasopharynx, and in case of necessity using leptazol—I am, etc.,

Harrogate

W S THACKER NEVILLE

Sulphonamide Sensitivity

SIR—I would like to support the warning given in your leading article (Aug 19, p 248) about the dangers of sulphonamide sensitivity. I have recently seen several cases in which rashes have been produced by sulphaguanidine so that the patient who was originally suffering from a mild diarrhoea has been off work for weeks because of his skin. In some of these cases the patients already knew that they were sensitive to sulpha drugs but did not realize what was being given to them, which shows the importance of taking an accurate history before starting treatment. Sulphaguanidine is a great saver of man power, but neither it nor any other sulpha drug should be given until it is certain that the patient has had no previous skin reaction. There are, of course, exceptional cases where the risk must be run.

One point in diagnosis is worth recording. Rashes from sulpha drugs are often difficult to diagnose from German measles, especially as glandular enlargement is said to occur in both. However, a careful search will often show small papulo-vesicular lesions on the backs of the hands and fingers in the former which will settle the diagnosis—I am, etc.

F F HELLIER

Lieut.-Col. R.A.M.C.

Rate of Artificial Respiration

SIR—Now that uniformity as regards the timing of Schafer's method appears to have been attained, may I enter the lists and point out that no uniformity exists as regards rate either in this or in Eve's rocking method. Whereas the St John's textbook and those of the Royal Navy, Army, and Royal Life-Saving Society advocate 12 times a minute—approximating normal respiration on—the B.R.C.S. *First Aid Manual* advises 15 to 18 times a minute—a possible 50% increase. Again, Dr Eve, in a communication in the *Lancet* (about April, 1944), recommended 10 double rocks a minute—4 seconds head down, 2 seconds feet down. But Surg. Lieut. Gibbens (*Journal*, Dec 26, 1942) advocated 12 to 15 double rocks a minute—again a possible increase of 50%—whereas your leading article (June 24, 1944) suggests 8 to 9 rocks a minute—4 seconds head down, 3 seconds feet down.

Truly the way of the instructor is hard, and he may well join with Macbeth and say

we do but teach

Bloody instructions, which being taught, return
To plague the inventor.

—I am, etc.,

Guildford

J L BARFORD

Postgraduate Medicine

SIR—Dr Walshe's considerations on higher or postgraduate medical studies are bound to make a great impression on the readers of the *Journal*. They are so carefully collected and so ably presented that one's first reaction is to applaud the resonant note. It is only on deeper percussion that the tympanic sound becomes apparent. The reason is the common one—the premisses are fallacious.

First, he presumes that medicine is a science. Although it should have a scientific basis, it is still, thank God, an art—an art which cannot be mastered in the monastic precincts of "the good postgraduate school" set aside "for advanced and original studies." Secondly, there is the presumption (in both senses of the word) that the general practitioner is of lesser breed, unworthy to be associated with the blue-blooded aristocracy of the "consultants and specialists." Where, oh where, would medicine be now but for the host of general practitioners who have been responsible *while in general practice* for the advancement of our knowledge? One has only to mention such names as Edward Jenner and James Mackenzie utterly to refute such an aspersion. Lastly, there is, without a shred of evidence, the wholesale damnation of "refresher courses." Admittedly these courses vary in their value. Some are bad, some indifferent, the majority are extremely good. Let Dr Walshe do a little research work on his own, and take, say, fifty doctors who have never attended a refresher course and fifty who make a habit of it, and then judge, on his own standards, which are the better doctors—I am, etc.,

Torquay

B VENN DUNN M.D., F.R.C.S.

SIR—In your issue of Sept 2 Dr Walshe makes some interesting and important points about the future of postgraduate medicine. Writing as a teacher, he rightly stresses the value of the special hospitals and the need to encourage research instead of creating cram courses and diploma machines. From the student's aspect, however, there are also one or two things to say. While it is essential to have schools devoted like that at Hammersmith, to the advancement of higher medicine it is also necessary to have some institution which caters primarily for the need of the general practitioner. Short refresher courses given by a number of consultants and specialists without a knowledge of the problems arising in general practice, do not benefit those who attend them. The student picks up a scattered handful of unrelated facts, many of which are not applicable to his daily round. A syllabus created by those with intimate knowledge of the requirements of the general practitioner, from personal experience might be more useful to the postgraduate. Also, it is certain that the short intensive course is less stimulating and informative than say an afternoon a week for three or four months spent in the out-patient department and wards of a hospital as clinical

assistant to an honorary physician or surgeon: The intervals between visits give time for meditation on what has been seen.

As practical therapeutics is an important part of general practice, facilities for doctors to learn such things as the injection treatment of piles, simple physiotherapy, and so on, would be very welcome. At present, students waste a considerable amount of time finding the clinics or departments most suited to their needs.

Let us hope, therefore, that in the brave new world of post-graduate medicine there will be some place which caters for the conscious inadequacy of the many, as well as facilities for the more ambitious few.—I am, etc.,

Leighton Buzzard.

TREVOR H. HOWELL.

Disadvantages of Lay Psychotherapy

SIR.—In the *Journal* of Sept. 2 a letter was printed supporting the use of lay psychotherapists, and claiming that medical knowledge was not necessary provided the therapist knew sufficient about psychotherapy.

Now "anxiety state" is a condition commonly treated by psychotherapy. Briefly the symptoms of an anxiety state may be listed as follows: *Bodily Symptoms*.—Tachycardia, tremor, sweating, brisk tendon reflexes, raised blood pressure (temporary), diarrhoea, dyspepsia, enuresis, impotence, and so on. *Mental Symptoms*.—Insomnia, headaches, vertigo, all sorts of fears, inferiority feelings, hypochondriacal complaints, etc. Often the patient presents only one main symptom, so that it is necessary to have a knowledge of the differential diagnoses of, say, tachycardia, tremor, dyspepsia, and enuresis, and in my opinion this entails a great deal of both medical knowledge and experience. Again, even when an anxiety state is frankly present, it has to be diagnosed from organic disease, as early general paralysis, cerebro-arteriosclerosis, thyrotoxicosis, chronic toxæmias, cerebral injury, etc. Further, an anxiety state may be but a feature of schizophrenia, involutional melancholia, neurasthenia, cyclothymia; or it may be intermingled with hysteria and obsessional disorders.

It therefore appears to me that anyone who undertakes to treat a mental illness should have a sound knowledge not only of psychotherapy but also of psychological and general medicine. There may be a few lay psychotherapists who have had good results, but I think the idea that lay psychotherapists are qualified to treat mental illness is a wrong one, and it is to prevent this idea gaining ground that I have been prompted to write this letter.—I am, etc.,

Edinburgh.

KENNETH HAZELL, M.R.C.P., D.P.M.

SIR.—The suggestion of Dr. D. Stanley-Jones that psychotherapists should be trained without their first having acquired a general medical training is surely both hazardous and unimpractical of the essentials of successful psychotherapy. I would have thought that it was by now generally accepted that physical and mental illness often go together, and that it was realized that psychotherapy cannot be safely practised without first a correct diagnosis. In which case it surely follows that a psychiatrist requires to be an experienced clinician and neurologist in order to differentiate organic disease from mental illness before he is able with safety to diagnose the different forms of mental illness.

I suppose it would be possible for the psychiatrist to advise the "lay" psychotherapist on the form of treatment, but even so the latter would surely be working at a disadvantage, since he would not be in a position to begot the same confidence that a medical practitioner might be able to gain.—I am, etc.,

M. F. BETHELL, M.R.C.S., L.R.C.P.

Morale in the Services

SIR.—Temp. Surg. Capt. Curran and Temp. Surg. Lieut. Garmany, writing on "Post-operational Strain in the Navy" (*BMJ*, July 29, p. 144), were unfortunate in their use of terms when comparing factors contributing to good morale in the Navy with that of the Air Force and Tank Corps. To describe either a tank or an aircraft as a "contraption" shows that in their own admirable devotion to the Senior Service they have

lost an appreciation of that wider view which all good psychiatrists should possess. It should be a matter of common knowledge that tank crews feel in a "vividly personal way" about their machines. The five members of a Churchill, for instance, have usually spent two or three years as a small team in constant charge of their vehicle, which they come to regard as an extension of themselves. It is the practice in the Tank Corps to change personnel who "do not fit," thus increasing the idea and feeling of a happy team.

From the numerical point of view it is fairer to compare a ship with a regiment, but although at first sight it might appear that men are more devoted to a ship, I doubt whether in practice this is the case. Even with such a large unit as a Division great personal pride is felt. There is considerable satisfaction experienced in being a "Desert Rat," probably more than in a comparable naval formation. As one officer aptly put it, "It would be a hell of a blow to take down the Divisional sign!"

I have no figures to support this criticism, but I doubt whether the writers had any evidence to support their own attitude towards this particular problem.—I am, etc.,

A. S. THORLEY,

Major, R.A.M.C., Psychiatric Specialist.

Military Psychiatry

SIR.—Lieut.-Col. Craigie's article on military psychiatry and his frank reply to Dr. Shaw's criticism have illustrated the great defect in Service psychiatry. It is clear that in the Services non-medical considerations are allowed to override sound principles of psychiatry to the inevitable detriment of the patient. While it is true that Service considerations will sometimes interfere with correct treatment in other branches of medicine, the conflict does not occur as frequently in somatic medicine as it does in psychiatry.

Since it appears that the war—in Europe at least—will shortly be over, it would be academic to pursue this issue if it were not that Service psychiatric practice will certainly have a considerable influence on post-war medicine. During wartime the psychological element in illness has received much more attention than formerly, and there will be a continuing demand for the help of psychiatrists in dealing with a great variety of minor illnesses, especially those psychosomatic and neurotic diseases which cause so much wastage of man-power in industry. The demand for psychiatrists will presumably be met very largely from those who have been trained under Service conditions. It will be a social disaster if they take with them into civilian practice the Service attitude towards their patients.

It may seem that I am unduly alarmist in suggesting such a possibility. A quotation from Curran and Guttman's recent textbook on psychological medicine provides evidence in support of my fears. They suggest that:

"Social changes . . . may well lead the community to demand more of the individual . . . and to permit him less freedom of choice and action. It is also probable that what are in fact neurotic reactions to economic stress or to the continuance of regimentation in civilian life will be rationalized as being due to war service and will result in claims for pension and compensation. The wartime orientation of the medical profession as regards the emphasis on its duty to the community rather than to the individual will need to continue in order to deal satisfactorily with problems of this kind" (p. 141, op. cit.).

It requires little imagination to foresee that a social system demanding the "continuance of regimentation in civilian life," in which the industrial misfits are dealt with by a corps of psychiatrists whose first duty is to the "community," would be uncomfortably like the totalitarian regimes of the Continent. If, in addition, the psychiatrist's duty to the community is reinforced by his enrolment in the State Medical Service, so that he lacks even the monetary inducement to put his patient first, then individual liberty will be still further menaced. Since it seems inevitable that society will be much more planned in the future, I hope that the medical profession will be concerned to mitigate the pressure of such planning when it bears too heavily on the individual, and that once the stress of war is over the first duty of a doctor will again be to his patient.—I am, etc.,

Carlisle.

J. BERNANT PHILLIPS.

Service Medicine

SIR.—The letter from Dr. P. B. Corbett (*Journal*, Sept. 9) is revealing, if revelation was necessary. Of course the advantages of the R.A.F. Medical Services, and those of the R.N. and the Army, are great from both the patients' and doctors' points of view. No one doubts it. But there are "buts."

(a) The complete history sheet is of the greatest value while the man is in the Service. If and when he is discharged it becomes so much waste paper. The man is not told the grounds on which he is discharged, nor the findings of a medical board. His medical attendant is equally left in the dark. (b) Expensive drugs and appliances are supplied generously and promptly. (c) The observation wards are the greatest boon. (d) Specialists of high standing are always on tap. (e) Adequate trained clinical and clerical assistance is always to hand. Obviously all these are admirable from both the patients' and the doctors' points of view. They are what the medical profession are pressing for through the B.M.A., and they are what the Government are extremely unlikely, and probably unwilling, to provide on account of the cost.

In wartime the civilian has little value in comparison to the man in the Services; and so far the same appears to be the official attitude in peacetime. One further point is that Dr. Corbett appears to be fortunate in his superior officers (which is not always so); but would it be equally pleasant, or work so well, if those superiors happened to be a Ministry official, an appointed administrative officer, or some "local authority"? The majority of doctors with experience of such conditions think it would not.—I am, etc.,

Deddington, Oxon.

G. M. HODGES.

SIR.—On reading the letter by "Temporary Serving Officer" (Aug. 19, p. 255) one can only assume that he has something wrong with his make-up or that he has had a bad time at the hands of Service medical administration or that he has not obtained the promotion and recognition to which he considers his professional ability entitles him. It is also obvious that he has little or no knowledge of either Service or civil medical administration, or he would hardly be willing to hand it over to laymen. It is against rash and ill-informed statements such as he has made that we have to be very guarded, especially at a time when we are fighting for the control of our own professional destiny.

The sudden and rapid expansion of the Services, and the difficulties under which the civilian medical services have accordingly had to work, have called for and obtained the highest administrative capabilities. It is, indeed, a matter for congratulation rather than the abuse which your correspondent has seen fit to heap upon it. Does he seriously suggest that the organization of the Army Blood Supply Centre or the evacuation of thousands of casualties from Normandy—to name two problems only—could have been dealt with by laymen? Surely the officers who devised the policy in these two cases and their assistants who administered it are worthy of the rank and pay which go with it.

It is also necessary to point out that the medical administrator's duty towards the sick does not—like that of the hospital clinical staff—end with the patient's discharge from hospital. He has to peruse carefully those despised "redundant documents"—sample documents which it appears that many temporary serving officers are quite incapable of completing properly—in order that the sick man's interest may be fully safeguarded in years to come.

Another point upon which your anonymous correspondent is quite ignorant is that most Service medical administrators are the representatives of the profession on formation headquarters staffs. In this capacity they not only have to administer policy laid down by higher authority but also make decisions on domestic matters in their own formations. It is therefore obvious that they have to be not only doctors but men of considerable experience in Service matters. It is also obvious that they must be given sufficient rank in order that medical policy may be fully stressed and enforced. It is in this way that the despised ex-regular officer has been of the utmost value to the State. That there are misfits in all branches of the Service cannot be denied—there always will be. "Temporary Serving Officer" would appear to be one of them. My own

experience of Service administrative medical officers is that they have been kindly, helpful, and co-operative, but men who do not suffer fools gladly.

There is no doubt that some form of State Medical Service is coming, and the profession is agreed that its administration must be in the hands of doctors. The administration should be neither master nor servant of the profession, but an integral part of it; one part cannot work without the other. Therefore let the medical policy of the State be devised by representatives of all parties concerned, duly appointed in accordance with democratic principles, let its administrators be well-qualified doctors who have a flair for this kind of work, and let all branches of the profession work together as a team for its professed ideals.—I am, etc.,

C. H. PAULI,
Major, R.A.M.C.

Medical Services—Home and Colonial

SIR.—Readers of the *B.M.J.* who have had any lingering doubts of the democratic outlook of its editorial panel (and these doubters have not been few) must surely have had those doubts dispelled during the past year by the publication *inter alia* of Dr. Geoffrey Bourne's several articles on State medicine, and more recently by the letters of Dr. H. B. Morgan on July 1 on the Colonial Medical Service, and by "Temporary Serving Officer" on Aug. 19 on Service medicine. The ethical and political importance of this stand should be appreciated by all doctors, especially those in the Services at home and in the Colonies, as these have no other organ through which to voice their opinions and to afford them moral support. I have had many opportunities to hear from my colleague in the R.A.F. evidence which confirms the views of "Temporary Serving Officer." But it is of the Colonial Service I would write, having served in the Gold Coast from 1925 to 1942. "Temporary Serving Officer" has been obliged to preserve his anonymity, but I am not so handicapped, having resigned from the Colonial Medical Service in 1942.

I would first recall Dr. Morgan's letter. Colonial medical officers who read that letter were not at all likely to have misunderstood its implications, nor were they likely to be distressed by his alluding to the Colonial Service as the "worst medical service in the world." They might, however, have been more pleased had the denouncement been accompanied by precise evidence. Therefore I would myself recall certain faults, and offer some constructive criticisms of the Service as I knew it in West Africa.

At the outset a critic of the Colonial Medical Service should bear in mind its history and constitution and its character—which is somewhat military. Uncritical and unquestioning obedience is expected. Enterprise or initiative is not required. Until recent years medical officers entered the Service to treat only the officials and their families. Against this imperial background an officer of conservative mind might express gratification with the rate of progress and with the transition to a medical service for the whole community. But to a modern and democratic medical mind much fault is still to be found. The observations made hereunder represent the opinions expressed by many medical officers in the course of years.

(i) The medical service is subordinate to, rather than complementary to, the political administration (which is itself subordinate to trading interests—as all may perceive). It has not, and never has had, a comprehensive health plan or policy for the colony as a whole, and there has been neither purpose nor goal to inspire M.O.s; merely dull routine (although an officer may engage in research on his own initiative). (ii) It is mainly because of this that the sole official record of work done is the scrappy annual report furnished by the director, together with that unscientific compilation of figures, Medical Form I. (iii) The personal relationship between the director and the medical officers has usually been a poor one. His office, that of an administrator, removes him from professional contact and from interest and sympathy in the work of the medical officers. A keen professional interest, I believe, there never has been. The following personal experiences may illustrate these points:

(i) In 1933 I worked keenly and became fairly expert in the problems of sleeping sickness and its distribution in South Mampoussa in the Northern Territories. By the end of the year I had drawn up and submitted a programme of bush clearing to cover a wide area. Thereupon I was removed and replaced by an

M.O. who had never been in an out-station before; a *tired* officer who had asked for a rest from a busy hospital! (I would not suggest that such ineptitude is usual, but it happened.)

(ii) In 1936, from Oda in the Ashanti forest, I submitted a lengthy report to the director on the incidence and course of a fatal childhood pellagra syndrome prevalent in that region. About a month later I succeeded in having the report returned to me. It was unacknowledged. Some two years later I learned that in that year—1936—not thirty miles away from me, Clarke, a keen biochemist, was investigating (at his own expense) the experimental pathology of a similar condition in rats. Had we known of each other's work useful collaboration might have been arranged. This experience gave me much food for thought on the need for official interest in medical research on the Gold Coast.

(iii) In 1939 I was seconded to conduct a diet and nutrition survey of natives in selected areas of the Gold Coast. In April, 1941, I submitted a 200-page report covering two years' investigations. This report, although approved by the Nutrition Committee in Accra, was not sent home. Inquiry at the Colonial Office during leave left me in no doubt that this action was in accordance with their wishes. Therefore I resigned from the Service.

I would now, with the detachment which maturity brings, on behalf of my silent serving colleagues, make certain constructive criticisms.

1. The role of Director of Medical Services should be to direct clinical medicine and research. Therefore the officer appointed to that post should have a positive record of achievement in the clinical field. The financial and administrative duties to which he normally gives so much time should be undertaken by administrative officers. (In a general way it is true that science is rated secondary to its financial costs, which receive an inordinate amount of official attention.)

2. The Director must needs be appointed by Government; yet the appointment might be made subject to a majority approval vote by all medical officers confirmed in rank. I am conscious of the revolutionary nature of this proposal; yet any courageous doctor may earnestly inquire, "If the Service is to develop on truly democratic lines why should *not* the responsible doctors be consulted?" (The need for such a change step is to be found in the appointments that have been made hitherto.)

3. The greatest professional disadvantage of medical officers in West Africa is the lack of opportunity for exchange of views and ideas. In 1936 many senior M.O.s wrote a proposal to the then D.M.S. requesting that clinical meetings be held once or twice yearly at regional centres—Accra, Sekondi, Kumasi, Tamale. The political officers hold yearly conferences. The request was ignored.

4. A medical service with some 50 medical officers serving some three million people should have at least one highly qualified medical registrar at headquarters, assisted by a special clerical staff, whose duties would be to aid the director in guiding research, to collate clinical records, to criticize, and to advise M.O.s. This expert staff could edit a local medical journal. (The *West African Medical Journal* died in 1927 because there was no staff available to run it.)

5. A medical library of books and periodicals should be provided. This could be suitably controlled by the officers above mentioned with additional clerical library staff. (Hitherto medical officers have been able to obtain the loan of some books from Accra by courtesy of the pathologist.) It would seem in the official view that medical journals and a library can be conducted by officers in their spare time; or, it might be truer to state that such institutions do not interest Government at all.

6. Publication of, and verbal expression of, professional views and opinions should be *free*. (It should be of the keenest interest to doctors at home that similar repression, or suppression, is contemplated in the State Medical Service which Government proposes to form in England.)

In conclusion, if the Colonial Medical Service were permitted to develop on democratic lines it would render an excellent account of itself.—I am, etc.,

F. M. PURCELL, M.D., F.R.C.P.I., D.T.M.&H.

Council of the R.C.S.

SIR,—Latterly the Council of the Royal College of Surgeons of England has shown its desire to make itself more representative of the many facets of British surgery, and many Fellows and Members of the College appreciate its recent action in co-opting one of the Members to be present at its deliberations (*B.M.J. Supplement*, Aug. 5, p. 31). As opposed to this liberal action, however, it is unfortunate that, previous to its recent election, the Council circulated to the Fellows (who are the electors) a note to the effect that it deprecated canvassing for the election "whether personally or by institutions or associations." Such a ban, if obeyed, is likely to have far-reaching effects on the constitution of the Council, for

although most Fellows regard personal canvass with distaste yet "group canvassing" for the purpose of securing adequate representation of the various specialties of surgery, as well as provincial and other types of geographical representation, essential if a widely scattered electorate of some 2,500 Fellows is to unite for the purpose of building up a Council representative of the many interests involved.

Formerly, the Council was representative almost solely of London surgery, with only an occasional representative of the Provinces; but under the influence of Moynihan provincial surgery received its due recognition, and this was reflected in the composition of the Council, which for some years has had about one-third of its members drawn from provincial schools. This has only been achieved, however, by the combined action of a group representing the provincial medical schools seeking to secure representation of these more or less isolated bodies. The standing of the great London medical schools, with the traditions and loyalties, places them in such a strong position in this election that to deny such a canvass to the smaller London schools and the provincial schools inflicts a real hardship and practically excludes them in future from the probability of adequate representation. Even under circumstances operative until recently, it is notable that, in 1942, while on London hospital had four surgeons on the Council at that time three provincial schools were unrepresented.

The Council has no power to enforce such a ban, and by its imposition places itself in an invidious position by seeking to withhold from its scattered electorate one of the means by which the various interests involved may come to a decision as to their representation. If, as I believe it does, the Council wishes to make itself representative of British surgery in the widest possible sense, it should welcome among its Fellows all reasonable activities to promote this end and not seek to guide them too zealously.—I am, etc.,

Birmingham.

SEYMOUR BARLING.

Wet Babies

SIR,—An obvious fallacy under the heading "The Crying Baby" in Dr. Doyne Bell's lecture printed in your issue of July 29 almost prevented my reading the text of an instructive article.

Surely the treatment for a hot baby and a wet pillow is a dry pillow and a less hot baby—and incidentally the consoling presence and touch of the baby's mother. Is it not the exception to find any abnormality on examination when the mother complains of her baby crying? Seldom has she troubled to find out whether the baby is thirsty, hungry, too hot or too cold, or only frightened.

May I suggest that a common cause of "momentary discomfort" is a full bladder? Some time ago a midwife said to me that a baby never passes water in his sleep. The assertion surprised me at the time, but I have since demonstrated its truth in the case of one baby. The very young baby wakes and cries at the discomfort, and can often be picked up before passing water, with the early establishment of some degree of control. More important, the baby is reassured, comfortable, and will settle happily to sleep until the time of the next feed. The use of sedatives can only inhibit this natural phenomenon. Six months is an early age at which to take drugs for non-pathological conditions and as a substitute for human contact.—I am, etc.,

Zennor, Cornwall.

S. M. HALLIDAY.

Tie the Cord

SIR,—I have been interested in the recent correspondence under the heading of "Why Tie the Cord?" in the *Journal*, and a recent tragic experience has convinced me more than ever of the necessity for tying the cord.

Within the past six weeks I delivered a patient spontaneously of a living child at 11 p.m. When delivering the child I remarked on the extreme thickness and gelatinous nature of the cord, and, as a result, tied the cord in three places, using triple reef-knots firmly tied. Just over one hour later I examined the child and all was well, and I left the nursing home. One and a half hours later I was called back urgently to the home because the child had had a very severe haemorrhage from the cord, from which it died some three hours after delivery and before transfusion could be instituted. Examination

tion showed that the cord had contracted down considerably, and that haemorrhage had occurred through the umbilical vessels. Not one of the ligatures had cut through the vessels, and the haemorrhage appeared to be due entirely to the fact that the ligatures became relatively loose due to the contraction within the cord.

While undoubtedly it may be unnecessary to tie the cord in some cases, I think a case such as this demonstrates the fact that not only should the cord be tied in every case but that it should be tied very securely indeed, and, most important, that it should be watched carefully for some hours afterwards.—I am, etc.,

London, W.1.

CHARLES D. READ.

W.C. Equipment

SIR.—Is it not time that lavatories be fitted with adequate facilities for washing oneself after defaecating, following the example of the French bide? The use of toilet paper is insufficient for scrupulous cleanliness, and it probably has a local irritant action on the delicate muco-cutaneous junction of the anus. Tiny excoriations and fissures produced in this way are liable to infection. It would be an advantage if some soft and absorbent material could be used instead of toilet paper.—I am, etc.,

G. A. POWELL-TUCK.

The Young Married Doctor

SIR.—I think I am speaking for a large section of the younger members of the profession, who, owing to war service, have already been separated for a considerable time from their wives, when I say that there are many of us who, although desirous of continuing an interrupted hospital career when we return, feel we will be forced to deny ourselves this owing to the anomalous situation that still obtains, which makes it impossible for junior hospital appointments to be held by married men who wish to continue to live with their families.

It seems that the hospitals will be deprived of the services of many who aspire to specialist work, who, on the above account, have been forced to forgo their ambition. Would it not be fair to these men if some consideration were given to this problem; that, if married quarters cannot be provided, at least permission might be extended to facilitate their lodging in the close neighbourhood of the hospital with telephone communication?—I am, etc.,

TOM BARNES.

Early Days at Johns Hopkins

SIR.—I have read with interest your leading article in review of the *Chronicles of the Johns Hopkins Hospital*, and in reading I missed the name of one brilliant son. Early in 1901, when on my first visit to the United States, I had the delightful privilege of dining with Prof. Osler and meeting at his table his distinguished colleagues, Halsted, Welch, and Howard Kelly. Among those present was a young surgical resident, Harvey Cushing, whose star in course of time was to give added lustre to the university and to the brilliant constellation of the "Big Four" of Sargent's portrait.—I am, etc.,

London, W.1.

C. GORDON-WATSON.

The annual report for 1942 of the Palestine Department of Health states that the birth rate was the lowest yet recorded. The infant mortality rate was higher, especially in the towns, than that of the previous year; but the general death rate was lower. There were five cases of plague—three of them infected in Haifa, in Northern Palestine, and fifteen in Jaffa and Tel Aviv, the first outbreak in this area since 1924. A few cases of smallpox were attributable to infection brought in from Syria and Lebanon, where the disease was prevalent; and a sharp outbreak occurred in the Tulkarm district, caused by returning pilgrims from Mecca. Land quarantine was imposed, and 270,000 persons were revaccinated within four months. The year 1942 showed the highest incidence of enteric fever since the British occupation: 4,065 cases were notified with 373 deaths. It is suggested that two factors played a leading part in the spread of the disease: military requirements caused unusual movements of labour; and, as a result of the high cost of living, much food was eaten which in normal times would have been regarded as unfit for human consumption. In all, 178,000 persons received protective inoculations, and the authorities hope to extend this measure.

Obituary

JOHN DODDS PRICE, M.R.C.S.

Dr. John Dodds Price died at Ferring, Sussex, after a painful illness, aged 79. He studied medicine at Guy's Hospital and qualified M.R.C.S., L.R.C.P. in 1889. A large part of his professional life was spent in India. After his return to England Dr. Dodds Price, who had joined the British Medical Association a year or two after qualifying, served on the Council in 1926 and 1927 and also for two years on the Dominions Committee and two of its subcommittees.

Sir LEONARD ROGERS, F.R.S., writes:

May I pay a brief tribute to my old friend Dr John Dodds Price, who died on Sept. 1. Very soon after qualifying he went out to work on tea estates in the Bengal Duars and a little later took up similar work in the Nowgong District of Assam, where he completed nearly 35 years' service in India before returning. He rendered me invaluable help during my investigation of kala-azar in Assam in 1896-7, and it was his earlier action in placing newly recruited coolies on badly infected tea gardens in newly constructed lines a short distance from infected ones that gave me the clue to the disease being a house or site infection. He also demonstrated the value of demolishing infected lines and moving the healthy coolies alone to new ones, in stamping out the disease from a number of tea estates in the Nowgong district and saving the industry in that district from ruin, as recorded in a joint paper of ours published in the *British Medical Journal* of Feb. 7, 1914. During the war of 1914-18 he acted as civil surgeon of the Nowgong District in addition to his other work, and so great was his professional reputation that he was awarded a Kaisar-i-Hind Medal of the first class.

In addition to being a much-beloved medical practitioner John Dodds Price was a great sportsman and rode in amateur steeplechases in his bachelor days, and later became captain of his district polo team. When a boy he sang in Westminster Abbey and was trained as a tenor, but felt a musical career too hazardous because his mother was dependent on him. He was thus an all-round man, but a most modest one, who will be greatly missed by his many friends. After his retirement he was much crippled by progressive osteo-arthritis of one hip-joint, but bore his troubles bravely. He leaves a widow, a son, and a daughter to mourn his loss.

HARVEY FRANCIS, M.D., died at his home in Woodthorpe, Nottingham, on Aug. 4, at the age of 75, after a lengthy illness, borne with the fortitude, courage, endurance, and selflessness which had been his character through life. His medical education was at Durham University and St. Mary's Hospital, where he held the posts of resident obstetric officer and house-surgeon. For 47 years he practised at Arnold, on the northern outskirts of Nottingham. His practice was an extensive and varied one, comprising miners, shopkeepers, business men, and landed gentry: with all alike he was deservedly popular. He possessed a most attractive personality, always cheery, always helpful when serious trouble came, so that his patients learned not only to love him but to put in him the most complete confidence. He was a keen and conscientious worker, and right up to the time of the onset of his illness he continued to carry on his work with the same energy and devotion which he had always given. In addition to his large private practice Dr Francis held many appointments, including those of M.O.H. to the Arnold Urban District Council, which post he held for 40 years, and that of certifying factory surgeon. During the war of 1914-18 he was in medical charge of the Arnot Hill Hospital, Arnold, a hospital of fifty beds. His services to this hospital, so devotedly given, were recognized by the award of the O.B.E. His loss will be severely felt by his fellow practitioners in Nottingham and Notts, with all of whom he was deservedly popular. A keen cricketer in his early years, he frequently played for the local cricket club, and in his later years often attended the Notts County Cricket Club matches at Trent Bridge. He leaves a widow, three sons, and a daughter. Two of his sons were with him in partnership, the elder of whom is now carrying on the practice, the other serving as flight lieutenant in the R.A.F. in Italy. To them all we extend our sympathy.—W. R.

We regret to announce the death at his home in London on Aug. 8 of Dr. HENRY CARSON SMYTH. Qualifying in Dublin in 1911, his early professional life was spent in Ireland. He is still vividly remembered by old colleagues of Stevens's Hospital, where he was resident surgeon. He was liked by

all the students, and he displayed a lively interest in their work. In the mess he showed his wide general knowledge of the sciences, continually putting pointed and stimulating questions to his juniors. A colleague writes: Dr. Smyth's professional interests were wide, but he made a special study of venereal disease and dermatology. Some of his work is displayed in two papers on the use of salvarsan. In the last war he was civil surgeon at the Royal Military Infirmary and Portobello Military Hospital in Dublin. Later he served as captain, R.A.M.C., in Malta and Salonika, where he met Dr. Janet Park Walton, whom he married, and who has, especially in the final years of failing health, given him great assistance in his work. In 1918 Dr. Smyth settled down with his wife in general practice in Coldharbour Lane, London, where he soon became widely known and popular, and where he practised for twenty-six years. He was a member of the B.M.A. and a Fellow of the London Dermatological Society. All his spare time he devoted to the work of the St. John Ambulance Brigade, to which he was divisional surgeon, being lecturer and examiner for South London. He was an enthusiastic Freemason. Harry Smyth had a keen sense of humour, which helped to endear him to his patients, who often came to him for friendly advice as well as for medical attention. He was loved by children and animals, with whom there speedily sprang up mutual understanding and affection. Many of the people of Loughborough Junction and Herne Hill, to which he extended his practice in 1928, have cause to mourn the passing of a beloved physician and friend.

Dr. GUY FOSTER BARHAM, late medical superintendent of Claybury Mental Hospital, died on Aug. 30 at Gorran Haven, Cornwall. He began the study of medicine at Cambridge University, taking his B.A. in 1895, and went on to the London Hospital, qualifying M.R.C.S., L.R.C.P. in 1901. He graduated M.B. at Cambridge in 1903 and proceeded M.D. in 1912. He was for a time house-surgeon at the Poplar Hospital and started his career in psychiatry at the London County Mental Hospital, Long Grove, where he was serving as senior medical officer at the time when the L.C.C. appointed him to be chief of Claybury Hospital. Dr. Foster Barham was a member of the Royal Medico-Psychological Association; he joined the B.M.A. in 1918 and served for six years at headquarters on the committee appointed by the Council to consider lunacy law and mental disorders. He published papers in the *Journal of Mental Science* and in the *Archives of Neurology and Psychiatry*.

Dr. WILLIAM MARTIN FROBISHER, who had practised for over 50 years in Leeds, died in retirement at Headingley on Aug. 30. He was a descendant of Sir Martin Frobisher, the famous 16th century navigator. He studied medicine at Leeds and took the M.R.C.S. diploma in 1897; before settling in practice he held a house appointment at the General Infirmary at Leeds. His elder son, Dr. J. H. M. Frobisher of Forest Row, Sussex, served in the R.A.M.C. both in the last war and in this war, retiring with the rank of major.

Dr. WILFRID LOUIS REMI FLEMING, formerly chairman of the Guildford Division of the B.M.A., died at Pirbright, Surrey, where he had practised for a long time. The son of Andrew Fleming, of Kilmarnock, he studied medicine at Westminster Hospital and took a course in obstetrics at the Rotunda Hospital, Dublin, qualifying M.R.C.S., L.R.C.P. in 1895. Before settling in general practice Dr. Fleming was house-surgeon and resident obstetric assistant at the Westminster and house-physician at the Bethlem Royal Hospital. During the last war he served as medical officer at Henley Park Auxiliary Military Hospital; later he was for a time M.O. to the Bisley Farm School and Shaftesbury Home. A man with a strong sense of public duty, he was a justice of the peace for the county of Surrey and chairman of the managers of the Pirbright elementary schools. Dr. Fleming joined the B.M.A. in 1900 and was also a member of the Royal Medico-Psychological Association.

The death is announced of Dr. ALBERT PENARD LAYCOCK, who before settling in general practice in South-West London had spent ten years as a medical missionary. He was born at Versailles on Sept. 26, 1877, son of the Rev. J. M. Laycock, and had his early education at Plymouth College, Merchant Taylors School, and Monkton Combe School. Entering St. John's College, Cambridge, he took his B.A. (with first-class honours in the Natural Sciences Tripos) in 1898, and went on to the London Hospital, qualifying M.B., B.Ch. in 1902. He was then for a time superintendent of the St. Pancras Medical Mission until he joined the China Inland Mission, Changsha, Lanchowfu, in 1905. While working there he was for two years surgeon to the Chinese Imperial Maritime Customs. He died on Sept. 5 in Sherbrooke Road, Fulham.

The Services

Col. R. Hay, C.I.E., I.M.S., has been appointed an Honorary Physician to the King in succession to Col. H. E. Shortt, C.I.I. retired.

Major (Temp. Lieut.-Col.) J. A. Chapel, R.A.M.C., Reserve Officers, has been appointed M.B.E. (Military Division) in recognition of gallant and distinguished services in the field.

CASUALTIES IN THE MEDICAL SERVICES

Killed in action.—Lieut. Robert Russell Waddell, R.A.M.C.

Missing, presumed killed.—Temp. Surg. Lieut. William Hamilton Cassels Donald, R.N.V.R., Surg. Lieut. Derek Napier McKenz R.A.N.V.R.

Died on active service.—Major Charles Peter Mann, R.A.M.C.

Died.—War Subs. Capt. Benjamin David Berger, R.A.M.C.

Wing Cmdr. WILLIAM MILLIGAN died on Sept. 3 while serving an R.A.F. headquarters over-seas. He was born in May, 1894, studied medicine at Leeds University, and qualified M.B., Ch.B. M.R.C.S., L.R.C.P. in 1927. He entered general practice, and on Dec. 28, 1937, was commissioned as flying officer in the Medical Branch of the R.A.F.V.R. After his embodiment for war service on Sept. 30, 1939, Wing Cmdr. Milligan served at various stations home, and in 1943 was posted to command a station hospital.

DEATHS IN THE SERVICES

The death is reported of Major-Gen. Sir ERNEST ALEXANDER WALKER, I.M.S., K.C.I.E., C.B., at Duncan, British Columbia, the age of 63. Son of the Rev. A. Walker, senior Army Chaplain Church of Scotland, he was educated at the Forfar Academy at Edinburgh University and graduated M.B., Ch.B. with honours in 1901, took the M.D. in 1940 and the F.R.C.S.Ed. in 1912. He entered the Indian Medical Service in 1902, and during the war of 1914-18 he served in Iraq in 1915-16, was taken prisoner at Kut-el-Amara, and was twice mentioned in dispatches. In 1920-1 he was D.A.D.M.S. (Mobilization), was promoted to be Deputy Director of Medical Services in 1929, was appointed to the medical staff of the Eastern Command, India, in 1933, and succeeded to the Director-Generalship of Medical Services, India, in 1933, where he proved to be a capable administrator. He became Honorary Surgeon to the King in 1932, and a C.B. in 1934. He retired in 1935 and in the following year was made a K.C.I.E. for his long and distinguished service on the military side of the I.M.S. General Walker had published papers on various technical medico-military subjects. Among his recreations were shooting and fishing.

Dr. Ernest Jones writes: The death in India of Lieut.-Col. OWEN BERKELEY HILL, I.M.S., recently announced will cause grief to a wide circle of friends, to whom his kindly loyalty, exhilarating companionship, characteristic drollery and wit, had endeared him. He will be remembered in India as the institutor of valuable reform during the eighteen years in which he directed the European Mental Hospital at Ranchi, and as a pioneer in introducing modern psychology into that country. His work in mental hygiene, in which field he represented India in several international congresses, was also noteworthy. A certain intolerance of officialdom, manifested by a stream of saucy—though never malicious—retorts, greatly diminished the influence his progressive outlook might otherwise have had among the powers that be. He published a volume of psychiatric essays, dealing especially with the ethnology of Indian peoples, and a racy autobiography.

Universities and Colleges

UNIVERSITY OF SHEFFIELD

At its meeting on Sept. 8 the University Council received the resignations by (1) A. Rupert Hallam, M.D., of his post of lecturer in dermatology; (2) P. E. H. Howarth, M.B., Ch.B., and R. Peasegood, M.B., Ch.B., of their posts of temporary demonstrator in anatomy. The Council accepted the resignations with regret, and accorded its thanks to Dr. Hallam, Mr. Howarth, and Mr. Peasegood for their services to the University.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

Two lectures, under the auspices of the Imperial Cancer Research Fund, will be delivered by Prof. W. E. Gye, M.D., F.R.S., at the College, Lincoln's Inn Fields, W.C., on Thursdays, Oct. 5 and 12, at 4 p.m. His subject is "The Part played by Viruses in Cancer Causation." The lectures are open to medical practitioners, scientists, and advanced students.

No 35

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Sept 2

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year for: (a) England and Wales (London included) (b) London (administrative county) (c) Scotland (d) Eire (e) Northern Ireland. Figures of Births and Deaths are 1 of Deaths recorded in each infectious disease, for: (a) The 126 great towns in England and Wales (including London) (b) London (administrative county) (c) The 16 principal towns in Scotland (d) the 13 principal towns in Eire (e) The 10 principal towns in Northern Ireland. A dash — denotes no cases, a blank space denotes disease not notifiable or a return available

Disease	1944					1943 (Corresponding Week)				
	(a)	(b)	(c)	(d)	(e)	(a)	(b)	(c)	(d)	(e)

Deaths (excluding still births) Annual death rate (per 1 000 persons living)	5 649	414	569	170	106	3 504	482	480	177	118
Live births Annual rate per 1 000 persons living	6 167	410	822	339	22	5 959	718	904	391	271
Stillbirths Rate per 1 000 total births (including stillborn)	216	12	2	—	—	191	22	26	—	—

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary fever for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In England and Wales the incidence of dysentery, whooping-cough, scarlet fever and diphtheria rose by 120, 73, 66, and 35 respectively. There were 45 fewer cases of measles reported than last week.

The returns for whooping-cough in Gloucestershire rose by 39. Measles notifications decreased in most areas of the country, but Lancashire had 55 more cases than last week, and Northumberland 56.

A new wartime record for dysentery was set up during the week, when 419 cases were notified. The cases occurred over a wide area, and fifteen counties recorded 10 or more cases. The largest centres of infection were Surrey 46, Sussex 35, Buckinghamshire 31, London 27, Essex 27, Glamorganshire 25.

In Scotland there were 13 more cases of diphtheria than last week, making the third consecutive week for which an increase has been reported. Notifications of acute primary pneumonia went up by 42 and those of scarlet fever by 25. There were 22 fewer cases of dysentery, the largest returns being Glasgow 39 and Edinburgh 23. The number of deaths from gastro enteritis rose sharply during the week, and 53 of the total of 57 occurred in Glasgow. Deaths for the corresponding week last year numbered 12. The source of the infection is unknown, but as a precaution the M.O.H. has advised the use of dried milk for infant feeding.

In Eire the high level of notifications for diarrhoea and enteritis was still further increased, 151 of the 197 cases were notified in Dublin C.B. The rise of 52 cases in whooping-cough was due mainly to an outbreak in Clare, Tulla R.D. 30.

In Northern Ireland a small rise of 18 occurred in the notifications of scarlet fever.

Week Ending September 9

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1 251, whooping-cough 1 223, diphtheria 481, measles, 1 138, acute pneumonia 303, cerebrospinal fever 41, acute poliomyelitis 24, dysentery 622, paratyphoid 3, typhoid 7.

Correction

In last week's table the dysentery notifications for Scotland were given as 15. The figure should have been 115.

Medical News

It has been decided that the programme for the 1944 annual meeting of the Faculty of Radiologists must be curtailed owing to prevailing conditions. The meeting will be held at the Royal College of Surgeons, Lincoln's Inn Fields, on Friday, Sept 29, beginning at 10 a.m. There will be a discussion on the Government White Paper on a National Health Service at 2.30 p.m.

The 236th meeting of the Biochemical Society will be held in the Department of Biochemistry, University, Western Bank, Sheffield, on Friday, Sept 29, at 11 a.m.

A meeting of the Association of Clinical Pathologists will be held on Saturday, Sept 30, at the London School of Hygiene and Tropical Medicine, Keppel Street, W.C. Programme 11 a.m., Prof. A. A. Miles and Dr. Nancy Hayward, the specificity of the Nagler reaction and the general problem of wound bacteriology, 12 noon, Air Cdre. T. C. C. Morton, investigation of a case of eosinophilia from the Tropics (with demonstrations), 2 p.m., Sir Alexander Fleming, the laboratory control of penicillin therapy (with demonstrations), 3 p.m., (a) Lieut.-Col. Yale Kneeland, U.S.A.M.C., experiences with penicillin in infectious diseases, (b) Col. D. M. Pilburt, U.S.A.M.C., penicillin in the treatment of venereal disease, 3.50 p.m., Lieut. Col. J. S. Jeffery, R.A.M.C., commentary on Sir H. W. Florey's film on the treatment of war wounds with penicillin. Demonstration (on view 10 a.m. to 5 p.m.), Major J. Edwards, U.S.A.M.C., a case of coccidioidomycosis immitis.

The first lecture in the autumn programme of the 32nd annual series of Chadwick Public Lectures is to be delivered on Tuesday, Oct 3, at 2.30 p.m., at the Royal Society of Tropical Medicine and Hygiene, 26, Portland Place, W., when Lord Amulree, M.D., will lecture on "Water Supplies in Peace and War". Admission to all the Chadwick lectures is free, tickets are not required.

The following medical films will be shown at the Solarium, Grange Road, Bermondsey, S.E.1, at 8.30 p.m. on Tuesday, Oct 3, "Highland Doctor," "Blood Transfusion," and "Scabies." Any doctors wishing to attend will be welcome. No. 1 bus to Grange Road.

The North-West London Branch of the English New Education Fellowship will hold a meeting on Tuesday, Oct 3, at 7.45 p.m., when Drs S W Jeger and R W Cockshut will discuss schools and the State Medical Service. The meeting is open to the public without charge, and will take place in the School Hall, Hendon County School, Golders Rise, Hendon.

The National Council for Mental Hygiene has arranged a course of ten lectures on "The Psychology of Frustration and Fulfilment in Adult Life," to be held in London and repeated in Birmingham. The London series will be given at Caxton Hall, S.W.1, on Tuesdays at 5.30 p.m. from Oct 3 to Dec 5. The Birmingham series will be given at Friends' Meeting House, Bull Street, on Wednesdays at 5.30 p.m. from Oct 4 to Dec 6. The fee for a complete course is £1, single tickets, so far as accommodation permits, 3s 6d, obtainable at the hall before each lecture. Application for tickets for a course should be sent to the Secretary, National Council for Mental Hygiene, 39, Queen Anne Street, London, W.1, or to Messrs Dale, Forty and Co. Ltd., 80, New Street, Birmingham, 2, who are acting as agents for the Birmingham course.

The annual general meeting of the Association of Industrial Medical Officers will take place at the London School of Hygiene, Keppel Street, W.C., on Saturday, Oct 14, at 11 a.m. Morning session, 11 to 1, private business. Afternoon session, commencing 2.30 p.m., an address by Prof John A. Ryle, M.D., "Social Medicine as a Discipline."

At a sessional meeting of the Royal Sanitary Institute to be held in the Peirymount Cinema, Haywards Heath, on Saturday, Oct 14, at 10.30 a.m. a discussion on "Diphtheria Immunization" will be opened by Dr W. B. Stott, M.O.H., Cuckfield Rural District Council.

At the Odeon Cinema, Plymouth, on Sunday, Oct 15, at 11 a.m., a British Council medical film, "Surgery of Chest Diseases," will be shown. All medical practitioners, including British and Allied Services, are welcome. Address by Surg. Rear-Adm. G. Gordon-Taylor.

Chevrons for war service and wound stripes are to be awarded to volunteer stretcher bearers enrolled at hospitals in the E.M.S.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE EUSTON 2111. TELEGRAMS: *Articulate Westcent London*. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone, unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE EUSTON 2111. TELEGRAMS: *Articulate Westcent London*.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association, TELEPHONE EUSTON 2111. TELEGRAMS: *Medisecra Westcent London*.

B.M.A. SCOTTISH OFFICE: 7 Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Chinosol

Q.—What are the present opinions on and uses of "chinosol" now known as hydroxyquinoline sulphate? When I was in practice I used it continuously for all minor surgical cases and found it very satisfactory. Primary union of stitched wounds I looked upon as a certainty. It is quite non-irritating in any strength. Its disadvantage is that it attacks instruments. Is chinosol out of favour now? If so, why?

A.—Chinosol has a strong antiseptic but little rapid germicidal action, which is exerted mainly against Gram-positive cocci, Gram-negative organisms are much less susceptible. Solutions are acid, and it has therefore some local irritant action, but is certainly less toxic than many other commonly used antiseptics. So far as this country is concerned chinosol cannot be said to have fallen out of favour, for the simple reason that it has never come into use to a sufficient extent for the reverse process to be noticeable. There is no evidence in the literature of diminished popularity in the country of its origin. German papers in comparatively recent times describe its use for the treatment of wounds, infections of the skin, eye, and female genital tract, for throat carriers of *C. diphtheriae*, and for a variety of purposes in veterinary medicine. Without practical experience of its use no precise judgment of its merits or comparison with other antiseptics is perhaps justifiable. It may nevertheless be pointed out that chinosol has now some very formidable rivals. The newer acridine compounds are more powerful antiseptics,

sulphonamides applied locally have a well attested antiseptic action and are almost completely non-toxic, while penicillin combines its virtues in the highest degree.

Dangers of Screening and Radiography

Q.—How frequently can a patient have ordinary straight x-rays of the chest with a full-size x-ray machine assuming the ordinary exposures are used—i.e., weekly, fortnightly, monthly, what? My interest lies in the management of artificial pneumothoraces, where treatment and control may go on for five years or more. What are the short- and long-term ill effects due to one exposure to these x-rays? Is regular screening likely to be cumulative than regular x-raying?

A.—Under normal working conditions the use of radiology for the control of the management of artificial pneumothorax does not give rise to any anxiety about either local or general effects of radiation on the patient. The initial period may require several examinations within a few days, but after this the intervals gradually increase. If radiography or screening is employed to direct the cutting of adhesions, or tomography used for the visualization of location of cavities, then due allowance must be made for the additional exposure. While it is difficult to imagine a case in which a weekly radiograph may be necessary over a period of years, it too may be carried out without anxiety should real necessity arise.

Screen examinations are a different proposition. Presuming an interesting case, much more time may be spent screening than in being realized, and the quantity of radiation received by the patient may be considerable and uncertain. However, an experienced observer, knowing his cases, may secure the information he desires in a few seconds. Otherwise the patient would probably receive more radiation during average screening than in one exposure for a radiograph.

The ill effects from one dose over-exposure are local inflammation, alopecia (temporary or permanent), vesication, ulceration, and ultimately, possibly local malignancy—in that order and depending upon the degree of overdose. If the area is large there will be sepsis, toxæmia, and much pain. The ulceration may not heal and skin grafts may be necessary to repair. The lesser degrees of damage may result later in skin and glandular atrophy, telangiectases and late ulceration. The cumulative effect of long-continued small doses locally gives rise to skin and glandular atrophy, telangiectatic fissures, and warty growths that may go on to malignancy and metastasis.

General body irradiation such as may be received by those practising radiology under unfavourable conditions, or carelessly under favourable conditions, may give rise to leucopenia, which unchecked may lead to sterility and a fatal leucæmia. Some people are more susceptible than others, and there is also reason to believe that, in some, minimal body irradiation under similar conditions gives rise to an increase in the red cell count before the white blood count is recognizably altered.

The difference in the quality of the radiation (wave length) used in radiography and screening of the chest is such that it is an important factor in the question under consideration, but radiographic dose can be calculated precisely. The screening dose may be of a very varying magnitude under different conditions: in different hands.

With regard to protection, reference should be made to the report under the heading "Protection against X Rays" in the *Journal of the Royal Society of Medicine*, April 1, 1944 (p. 480), and to the recommendations of the British X-ray and Radium Protection Committee, which may be obtained free on application to the General Secretary, British Institute of Radiology, 32, Welbeck Street, London, W.1. See also the article "Effects of Radiation on Workers," by Ralston Patterson, *British Journal of Radiology*, January, 1943, p. 3.

Blood-pressure Readings

Q.—What is now generally accepted as being the correct method of ascertaining the diastolic blood pressure? Should the reading be taken when the character of the sound changes from snapping to a softer, more prolonged note, or when finally no sound at all is heard? Is it now generally accepted that the diastolic pressure is of greater significance than the systolic in cases of suspected arteriosclerosis? Does the diastolic pressure tend to vary as greatly as does the systolic at different times in the same individual? When may be taken as the normal range of diastolic pressures in aged from 20 to 60?

A.—The following recommendations for determining the diastolic blood pressure are contained in the joint report of the Canadian Society for Great Britain and Ireland and the American Heart Association (*Brit. Heart J.*, 1939, 1, 261). "The patient should be allowed time to recover from any recent exercise or excitement. Auscultation should be conducted during slow deflation, at the point where the loud clear sounds change abruptly to the dull murmur sounds should be taken as the diastolic pressure." It is impossible to be dogmatic about whether the systolic or the diastolic pressure

has the greatest significance in arteriosclerosis. Severe arteriosclerosis of the aorta tends to lower the diastolic pressure, whereas in early essential hypertension the rise in blood pressure may be evident only in the diastolic reading. The percentage fluctuation of the diastolic pressure is as great as that of the systolic in hypertensive patients, but in health a specific stimulus may have a different effect on the systolic and diastolic pressures. For instance, vigorous exercise often causes a rise in the systolic pressure while the diastolic pressure remains the same, or falls. The best statistics for the blood pressure in healthy individuals are those given by Symonds (*J Amer med Ass.*, 1923, 80, 232). According to him the range of the diastolic pressure at 20 years is 76 to 85 mm Hg, and at 60 years 82 to 90 mm Hg.

Acne

Q.—What is a simple and practical form of treatment for acne where large numbers of not very intelligent young people are concerned?

A.—Acne has two complementary and essential factors—an endocrine imbalance and a seborrhoeic skin. A 2% sulphur and salicylic acid ointment modifies the seborrhoeic fraction. It can be applied at night. Treatment on these lines is eventually successful by modifying one of the essential components.

Headache of Acromegaly

Q.—Can anyone suggest something to relieve the headache of acromegaly or of a pituitary tumour causing the symptoms? I have tried most of the usual analgesics without any effect. The condition of the patient is distressing to behold, and one feels so helpless.

A.—If a pituitary tumour is present, as might be indicated by optic atrophy or an enlarged sella turcica, operation should be considered, or, alternatively, radiotherapy. If there is no tumour, symptoms might be relieved by testosterone or stilboestrol, both acting by inhibiting the activity of the pituitary and possibly diminishing its turgescence or size. In an attempt to get a decisive response, large doses should be used—e.g., 50 mg intramuscularly daily of testosterone or 5 mg of stilboestrol. Later on methyl testosterone by mouth or stilboestrol by mouth could be tried.

Home-made Penicillin

Q.—Although *Penicillium notatum* is supposed to be a common mould I cannot find out where to obtain a pure culture. What is the composition of the best culture medium obtainable by purchase and where can it be bought? I have failed to get any from three laboratories. I wish to use a home-made culture of *Penicillium notatum* as a local application in gonorrhoea in a girl of 6 who is sulphathiazole sensitive (granulocytopenic) who has been benefited but not cured by sulphathiazole and whose mother is 7 months pregnant. I propose to inject the liquid culture into the vagina instead of using pot permanganate lotion. Why should not this culture in liquid be used as a local application until the supply of penicillin is abundant? I have an incubator.

A.—*Penicillium notatum* is obtainable from the National Collection of Type Cultures, Lister Institute, Elstree, Herts. For methods of preparing crude culture filtrate for local treatment the questioner is referred to a recent article by J. M. Alston in this *Journal* (May 13, 1944, p. 654). We know of no commercial source from which the necessary culture medium can be bought. An ordinary incubator will not serve for this purpose; the temperature required is 24° C. A good deal of other equipment and considerable knowledge are necessary for the production of a filtrate of known and adequate potency, and despite recent claims which have been made for the possibilities of home-made penicillin, the pitfalls involved are so numerous that it cannot be recommended for any serious therapeutic undertaking such as in the case described.

Clicking Mandible

Q.—My commanding officer has recently developed a very audible clicking of the mandible in the left temporo-mandibular joint. It occurs only when he is eating, and he can demonstrate it by "chewing the cud" as he puts it. It is becoming an increasing source of embarrassment to him for his fellow officers imagine he has a loose denture. He has dentures but they fit perfectly and are not the cause of the noise. He is aged 50, full faced and rotund. Could you advise me on the best treatment for such a condition?

A.—Clicking in the temporo-mandibular joint may be either bony or cartilaginous. In the former instance the cause is usually an arthritis of the joint, in the latter an abnormal or loose interarticular fibrocartilage. The treatment of the arthritic variety is along the usual lines which are adopted for arthritis elsewhere, but on the whole the results are disappointing. Sometimes the dentist can help by building up the "bite" posteriorly, so preventing too close closure of the jaws and thus relieving the joint surfaces. In cases

such as the present one, where a denture is worn, it is particularly important to see that the "bite" is correct, as an incorrect "bite" may not only be a causative factor in the production of the arthritis but may perpetuate the trouble. The use of a raised bite is of course only temporary. If the click is a cartilaginous one the same dental measures can be adopted, but in some instances a good result may follow surgical removal of the cartilage—an operation which is not as easy of performance as it may sound and which involves a definite risk of damage to the uppermost fibres of the facial nerve.

Desensitization to Foods

Q.—Could you let me know (in view of letters that have recently appeared in the *JOURNAL* on desensitizing patients suffering from pernicious anaemia to extracts of liver) (1) Whether it is possible to desensitize patients suffering from allergy to other food proteins by injection of extracts of such foods and if not why it should be possible only to desensitize against liver extracts and not other foods? (2) Whether it is possible to desensitize them by other means? (3) What is the method employed in the procedure? (4) If it is possible to desensitize them why do the textbooks all say it is not possible to desensitize them? (5) Why do allergic specialists also say it is impossible? (6) If it is possible to desensitize them do they remain desensitized for life? If not how long does the effect last? (7) Can desensitization do any harm? After undergoing a course may the patient become more sensitive in future to the substance than he was before?

A.—(1) There is some confusion of thought here. The patients with pernicious anaemia under discussion were sensitive to the injection of liver extract but not to the ingestion of whole liver by mouth. Their symptoms were not those of food allergy. Analogous is the fact that such people as bakers, who get asthma from the inhalation of dust containing wheat flour, may be successfully desensitized by injection of wheat extracts, whereas a similar procedure is usually disappointing in patients who are sensitive to wheat foods taken by mouth. Why it is so rarely possible to desensitize patients to foods by hypodermic injection is not known, but it may depend on the disparity between the dose which can be given by injection and the amount which is normally taken by mouth. In any event, desensitization to foods by the parenteral injection of extracts is only rarely successful.

(2), (3), (4) (5) Oral desensitization in which increasing doses of the food or an extract of it are given by mouth is perhaps a little more successful than hypodermic desensitization but it does not often succeed.

(6) Children often pass through a phase of sensitivity to a particular food and then grow out of it, but in the rare cases where active desensitization to food is successful in the adult, one would certainly not expect it to last for life. Sensitivity might well return within a month of omitting treatment. A more passive type of desensitization occurs when the offending food is eliminated from the diet for some weeks or months. In these circumstances patients may have no symptoms the first time they ingest the food again, but will probably have them if ingestion is repeated in 24 or 48 hours.

(7) There is no evidence that desensitization can do any harm, apart from the accidents of desensitization itself. On the contrary, experience with pollen therapy, which is the best known of all forms of desensitization, suggests that desensitization tends to produce some permanent lowering in sensitivity.

Phenobarbitone Poisoning

Q.—What is the treatment of acute phenobarbitone poisoning? Picrotoxin is usually advised but I have never been able to find the correct dosage.

A.—Picrotoxin is probably superior to most of the antidotes to barbiturate poisoning but it is more toxic. Large doses are tolerated in phenobarbitone poisoning. Thus whereas the BPC maximum dose is 1/25 gr., in barbiturate poisoning it is recommended to give doses of 1/6 gr. intramuscularly half hourly until muscular twitching occurs. Intravenous nikethamide is usually very efficacious and far less dangerous.

Local Anaesthesia and Dental Extraction

Q.—Is there any contraindication, and if so what, to the administration of a local anaesthetic—e.g. novocain—in dental extractions? Is prolonged nerve irritation ever likely to supervene?

A.—A local anaesthetic for the extraction of a tooth should not be given when there is an acute abscess, and it is unwise to inject into or through an inflamed area. When the outer plate of alveolus is dense it may be impossible to obtain a satisfactory anaesthesia by a local infiltration, especially in the lower jaw. In these cases a regional injection is better. Many patients have a definite dislike of any form of local anaesthesia and may feel faint and ill after the injection. Some seem to be hypersensitive to the adrenaline which is contained in most of the solutions. Local anaesthesia should not be used with patients who are in a low state of health. Arterio-

sclerosis and organic heart disease are also contraindications. Prolonged nerve irritation when it occurs is more likely to be due to trauma or sepsis than to the injection.

Endocrine Types and Measurements

Q.—Certain anthropomorphic measurements—e.g., span, vertex to pubis, pubis to heel, total height, circumference of head, chest, etc.—have been described by endocrinologists for the differentiation of endocrine types. Are these measurements, and the types which are distinguished from them, of recognized significance?

A.—The exact significance of the endocrine types is not yet generally recognized, though most authorities would agree that they have significance. The subject is one for research, and not for dogmatic statement. The same or similar measurements are also used for distinguishing quantitatively the races of mankind—white, black, yellow, etc.—and subdivisions—Alpine, Mediterranean, Nordic, etc.—and even in the major racial subdivisions there are overlappings. Attempts have also been made, notably by Kretschmer and more recently by Sheldon, to use similar measurements to distinguish temperamental types. Here also the whole subject is fluid. All the work on endocrine types is on rather a small scale, and much further work is required, though it is pretty certain that valuable data will be derived in the end. At present we have certain knowledge only in the case of the frankly pathological—e.g., Frohlich's syndrome.

The Diseases named "Pick"

Q.—What is Pick's disease? And what is polyserositis, and what are its signs and symptoms? Pick's disease is described in Beaumont's "Medicine" (1939) as "a diffuse proliferative peritonitis often associated with similar proliferative changes in the mediastinum, pericardium, and pleura". In Beattie and Dickson's "Pathology" (1943) Pick's disease is "a comparatively circumscribed progressive degeneration and atrophy affecting the cortical nerve cells of the brain".

A.—The use of eponyms is much to be deplored. They are responsible for great confusion and they tend to perpetuate outmoded conceptions. At least four men named Pick have had diseases called after them. Arnold Pick gave his name to a form of circumscribed atrophy of the brain, characterized by dementia, progressive degeneration of the higher faculties, and the development of aphasia. Alzheimer's disease and Arnold Pick's disease are two distinct subgroups of the condition known as pre-senile psychosis or sclerosis. The *Standard Nomenclature of Disease* unfortunately omits this form of Pick's disease in its list of eponyms, and the correct designation of the condition would presumably be "pre-senile sclerosis (Pick)".

Filipp Josef Pick gave his name to erythremia, the initial stage of progressive idiopathic atrophy of the skin.

Ludwig Pick gave his name to the Pick's cell in Niemann-Pick disease, which the *Standard Nomenclature* calls "xanthomatosis (Niemann-Pick)," and which English writers would prefer to call "lipoid reticulosis (cholesterol)".

Friedel Pick gave his name to polyserositis and more particularly to the syndrome now known as constrictive pericarditis—recurrent ascites, enlargement of the liver, and oedema of the lower extremities, with a heart of normal size and without orthopnoea. It is believed that in these cases the ascites is mechanical in origin, the heart is unable to expand and fill with blood in diastole and the venous pressure therefore rises. When proliferative changes occur in the pleura and peritoneum in association with adhesive pericarditis the term Concato's disease is sometimes used, this syndrome is very rare. It is impossible to draw hard-and-fast distinctions, as all the different varieties of chronic pericarditis and polyserositis are usually tuberculous in origin. It is, however, vitally important to pick out cases of constrictive pericarditis, in which the constriction of the heart is preventing diastolic filling, as the patient can be strikingly relieved by surgical operation.

Asymmetry of Labia

Q.—A girl aged 19 years is worried about her left labium being larger than the right since the age of 12 years. Examination findings confirm the patient's observations but there is no other abnormality. What treatment or advice should be given?

A.—Unequal development of bilateral organs is common, and, so far as the vulva is concerned, the asymmetry is mostly seen in connexion with the labia minora. It is presumed that such is the case here, and that the labia majora are not involved. Unilateral hypertrophy, unlike bilateral hypertrophy, of the nymphae is not likely to be caused by masturbation, and is to be regarded as a developmental anomaly. Any difference in size, if present, would hardly be noticed before puberty, since until that time the labia are undeveloped. This condition is not rare and has no special clinical significance. The patient should be reassured accordingly. No treatment is indicated unless the labium is so prominent as to get chafed by the thighs in that case partial or total removal may be required.

Oral Vaccines for "Colds"

Q.—Would you give me an authoritative opinion on the value of oral vaccines, with special reference to their use in the prevention of "colds and bronchitis"?

A.—There are two formidable objections in theory to regarding this proceeding as even possibly beneficial. One applies to cold vaccines however administered—it is simply that they do not contain the causative organism, which is a filterable virus. Granting that some colds are due to bacterial infection, or that virus colds are increased in severity or prolonged by secondary bacterial infection, then the ordinary type of cold vaccine has some semblance of applicability; but so many species are concerned, some of which include many distinct antigenic types, that such a vaccine cannot contain every organism likely to be encountered, and the more does contain the less, presumably, will be the degree of immunity produced to each. The second difficulty is in accepting the idea that a vaccine administered by the alimentary tract is going to immunize the respiratory tract. This is going further than Besredka who introduced oral vaccine for enteric fever on the assumption that the tissue involved in the disease itself could be locally immunized. The efficiency even of this proceeding is by no means generally accepted, but it is asking much more of a swallowed vaccine than it shall enhance the resistance of another tissue altogether.

The theoretical improbabilities involved are therefore extreme, but perhaps we do not know enough about immunity to catarrhal infections to condemn such a proceeding out of hand. There is some clinical evidence which, so far as it goes, appears to be favourable to the method. G. E. Rockwell *et al.* (*J. Lab. Clin. Med.*, 1937, 22, 912) claim to have reduced the incidence of colds greatly, as compared with untreated controls, by frequently repeated oral doses of a dried preparation containing many billions of four species of bacteria. The dosage employed by these authors was greater than that afforded by some commercially available preparations.

LETTERS, NOTES, ETC.

Wasp and Bee Stings

Dr O. H. BROWN (Guildford) writes: In the "Any Questions" section of Aug. 26 (p. 295) there was a reply under the above heading. On Aug. 20, 1919, the *Times* published a letter from Edward R. Speyer, M.A. (Oxon), F.R.S. Since reading that letter I have never had a moment's anxiety in dealing with wasp stings. There was an interesting correspondence on the same subject 19 years later to which I contributed two letters (published in the *Times* of Aug. 23, 1938, and Aug. 30, 1938). The *Lancet* (Oct. 11, 1941) also has a letter of mine on the subject. The gist of the matter may be summed up in the mnemonic—"A B, V W". alkalis for bee stings, vinegar for wasp stings.

Tug-of-war for Girls

Dr K. A. GRANT (Corsham, Wilts) writes: I read with interest your answer under the above heading in the *Journal* of Aug. 1 (p. 230). When in labour, a girl or woman is forced to undergo "comparatively long periods of stasis with contracted muscles and fixed thorax," so what harm will a tug-of-war, which lasts only a short time, do?

Wooden Bullets

Major H. B. C. POLLARD writes: The German "wooden bullet" so painstakingly radiographed by Dr Norman P. Henderson (*B.M.J.*, Sept. 9, p. 356) is incapable of producing injury at five yards, let alone 100! These are simply wooden "bulleted blanks" used in machine-guns where back gas pressure is needed to function the mechanism. They are in use in most Continental armies, and recent experiment at Woolwich Arsenal has shown that all German and Italian wooden bullets break up at the muzzle of a rifle and will not penetrate a cardboard screen at six feet. The whole business of wooden bullets is a soldier's story, but it is quite true that "the scattered fragments are not likely to be localized by radiological methods."

War Damage Contributions

H. S. owns a house which is mortgaged to a building society. It is used partly for professional purposes but "primarily as private residence." Is he liable to the whole or only to a part of the war damage contribution?

* The whole—and this would be the case if the property was used entirely for residential purposes. (The building society may be liable to recoup H. S. for part of his payment; whether and to what extent depends on the origin and relative amount of the mortgage.)

Correction

The third journal cited in footnote 3 to the leading article on problems of arboflavinosis (July 29, p. 153) referring to the work of Fitzgerald Moore should read *J. trop. Med. Hyg.*, 1937, 42, 109.

INFANTILE DIARRHOEA AND VOMITING

BY

M. B. ALEXANDER, M.R.C.S.

Grove Hospital, L.C.C.

AND

Y. EISER, M.D. Prague

Late North-Western Hospital, L.C.C.

This series comprises 140 cases of infantile diarrhoea and vomiting treated at the North-Western Hospital between June, 1943, and February, 1944, inclusive.

Summary of Cases

Age.—The infants were all under 15 months of age. Older children were excluded, since the disease is less common and invariably milder after the age of 15 months. When divided into five age groups, of 3 months each, 115—i.e., 82.1%—of the infants were in the first three age groups (0 to 9 months), the incidence falling sharply after 9 months. The severity, as judged by dehydration, was also greatest in the first 9 months of life, with 56.5% of dehydrated infants as compared with 16% in the age groups IV-V (9 to 15 months). This incidence corresponds with that found by Campbell and Cunningham (1941). There were no deaths among the infants over 6 months of age (Tables I and II).

1 died. Seventeen were admitted from other hospitals, of whom 12 were dehydrated and required intravenous therapy, and 1 died. The remaining 103 infants were admitted from home; of these, 43 were dehydrated and 6 died. We are unable to say what proportion of this last group were attending day nurseries.

Breast-feeding.—In this series 17 babies were breast-fed—8 wholly and 9 partially. This rather high incidence (12.1%) may be partly accounted for by the fact that cases were admitted from a maternity unit. Ages ranged from 1 week to 5 months in the case of the fully breast-fed infants, and from 3 to 10 months in the partially breast-fed babies. One fully and 4 partially breast-fed infants were dehydrated and required intravenous therapy. Breast-feeding was continued wherever possible. There were no deaths in this group. The illness was seldom so severe as in the artificially fed babies, and recovery was quicker and usually uncomplicated.

Dehydration and Severity.—Forty-nine infants were dehydrated on or soon after admission, and a further 20 became dehydrated more than forty-eight hours after admission—i.e., 69 cases in all, or 49.3% of the total. Of these, 26 showed evidence of extreme fluid loss, and 11 of them were collapsed on admission, exhibiting unmistakable signs of shock—cold, clammy skin; subnormal temperature; thin, thready, or imperceptible pulse; cyanosis of lips and extremities; shallow or sighing respiration—in addition to the usually severe dehydration. None of these 11 died. In 6 cases "orange" stools—an unfavourable prognostic sign—appeared for more than twenty-four hours during the course of the illness; 5 of these patients recovered and 1 died.

Duration.—The average stay in hospital was 30.2 days. No deductions can be drawn from this figure as many infants were, for administrative reasons, kept in hospital after recovery.

Mortality and Cause of Death.—There were 8 deaths in this series, giving a case fatality of 5.7% for all cases, or 11.6% of dehydrated cases. All these 8 infants were under 6 months of age, and 6 of the 8 deaths followed relapses. Post-mortem examinations were performed in 7 cases, and the causes of death found were: suppurative pericarditis (*Staph. aureus*), 1; circulatory failure due to excessive parenteral fluids, 2. The remainder of the deaths were classified as due to gastro-enteritis, complicated by otitis media in 1 case and by whooping-cough and secondary pneumonia in another.

Parenteral Infection

An attempt was made to investigate the presence and type of parenteral infection in these cases, based on the following criteria: (1) A history of parenteral infection preceding or concurrent with the onset of diarrhoea and vomiting. (2) Clinical signs of parenteral infection on admission—i.e., rhinitis, tonsillitis, otitis media, bronchitis, furunculosis, etc. (3) Bacteriological confirmation: nose, throat, and post-nasal swabs, and faeces and rectal swabs were taken from all infants on admission, and at intervals throughout the course of the illness, for bacteriological examination. In addition, swabs were taken from any discharge—e.g., pustules, otorrhoea. The urine was investigated in a few cases only, owing to the difficulty in collecting sterile samples of urine from babies with diarrhoea. All infants showing bacteriological evidence of intestinal infections such as bacillary dysentery and giardiasis were excluded from this series.

TABLE I.—Distribution in Age Groups: Death and Dehydration Rate in Each Age Group

Age Groups	No. of Cases	Deaths		Dehydration		Deaths among Dehydrated
		No.	Case Fatality %	No.	%	
I—0-3 months	33	4	10.5	23	60.5	17.3
II—3-6 "	49	4	8.1	27	55.1	14.3
III—6-9 "	28	0	0	15	53.5	0
IV—9-12 "	13	0	0	3	23.6	0
V—12-15 "	12	0	0	1	8.3	0
Total	140	8	5.7	69	49.3	11.6

TABLE II.—Incidence, Dehydration, and Mortality in Infants Under and Over 9 Months

Age in Months	No. of Cases	Dehydration		Deaths	Case Fatality %	Deaths among Dehydrated
		No.	%			
0-9	115	65	56.5	8	6.9	12.3
9-15	25	4	16	0	0	0
Total	140	69	49.3	8	5.7	11.6

Prematurity.—There were 8 premature infants in this series, all under 7 weeks old on admission. All 8 were dehydrated, and 7 required intravenous therapy. There were 3 deaths. The illness in all these cases was very severe, and convalescence slow. It is of interest to note that 3 of these babies had severe anaemia requiring blood transfusions, and that slow-drip transfusions of 200 to 250 c.cm. of blood were well tolerated after initial correction of fluid loss.

Sex.—Males predominated in the ratio of 3:2.

Season.—No deductions can be drawn from the number of admissions per month, as these were governed by external factors. Severity, as judged by dehydration, appeared to be highest in the winter months; but, again, no deductions can be made, as this series does not include the spring quarter.

Environment.—Twenty infants were admitted from institutions; of these, 14 were dehydrated, 8 required intravenous therapy, and

1. In 36 cases there was a history of parenteral infection immediately before the onset of diarrhoea and vomiting, and in 58 cases accompanying this—a total of 94 cases, or 67.1% of all. In many instances upper respiratory infections had been present in other members of the family before the infant's illness.

2. In 124 cases (88.6%) there was definite clinical evidence of parenteral infection on admission, mainly of the respiratory tract. There were 60 cases of otitis media. Only those cases in which a purulent otorrhoea occurred spontaneously or was found at myringotomy were included under the heading of otitis media. In 49 of these otorrhoea was present on, or within forty-eight hours of, admission. In the remaining 11 cases the otorrhoea appeared in 5 to 20 days; in all these 11 there had been evidence of upper respiratory infection on admission. Myringotomy was performed in 38 cases, and bilateral mastoidectomy in 11. Table III shows

TABLE III.—Incidence and Type of Parenteral Infection present in 140 Cases

Parenteral Infection	No.
Upper respiratory infection	29
Tonsillitis	12
Otitis media	20
Otitis media + other infections	40
Bronchitis	11
Pneumonia	2
Skin infections	8
Stomatitis	1
Conjunctivitis	1
Total	124

Note. Upper respiratory infection = rhinitis and pharyngitis.

the type and incidence of parenteral infection present in the whole series. In 88 cases (62.8%) pyrexia (temperature above 99° F.) occurred within twenty-four hours of admission. In 80 of these the pyrexia was associated with other evidence of parenteral infection, and in 8 no signs of parenteral infection could be found. Subnormal temperatures were observed in the 11 infants admitted in a state of shock. Temperatures of 101° to 103° F. sometimes appeared after the parenteral administration of plasma; we have tried to separate these from the initial pyrexia, which seemed to be due to the parenteral infection. It is noteworthy that 19 of 27 relapses (70.4%) were preceded by signs of parenteral infection and a rise of temperature above 99° F. Very often there was only a slight pyrexia of less than twenty-four hours' duration, which was followed in 24 to 72 hours by a relapse of the diarrhoea and vomiting, in some cases surprisingly severe, and with no further rise of temperature until the final agonal peak in the cases ending fatally.

3. Table IV shows the incidence and type of pathogenic organisms cultured from the upper respiratory tract on admission. The presence of *Staph. aureus* in the nose only was not regarded as significant, and these results are omitted from this table. The mere presence of

TABLE IV.—Incidence and Type of Pathogenic Organisms Cultured from the Upper Respiratory Tract

Organism	N	T	P.N.	P N	$\left\{ \begin{array}{c} N \\ \text{or} \\ T \end{array} \right.$	Ears	Ears + $\left\{ \begin{array}{c} N \\ \text{or} \\ T \\ \text{or} \\ P N \end{array} \right.$	Skins	Total
Haem. strep.	2	6	4	11	0	2	0	25	
Pneumo	2	1	4	5	7	3	0	22	
Staph. aureus	3	3	3	7	8	10	2	33	
Total	4	10	11	23	15	15	2	80	

Note N - Nose T - Throat. P.N. = Post-nasal.

these organisms in the nasopharynx does not necessarily imply an infection with them, but we feel that they are of significance if taken in conjunction with the clinical findings.

The discrepancy between the positive bacteriological findings in the ear discharges—30—and the actual number of otorrhoeas—60—may be partly explained by the difficulty of obtaining sterile cotton-wool swabs small enough to be passed through the infant's narrow meatus to reach the perforation or myringotomy wound. In the remaining cases only saprophytic organisms such as *Staph. albus*, diphtheroids, etc., were recovered on culture. Among the 11 mastoidectomies, swabs from the bone at operation were sterile in 7 cases. In the remaining 4, pneumococci, haemolytic streptococci, *Staph. aureus*, and *B. coli* were found each in one case. But although the incidence of bacteriologically proved mastoiditis may be no higher in diarrhoea and vomiting than that following otitis media in older children, mastoidectomy should always be considered in those cases of diarrhoea and vomiting in which pyrexia persists and the child fails to respond to sulphonamide and intravenous plasma therapy, provided the ear has shown some signs of inflammation and no other focus of infection has been demonstrated. The

operation carries very little risk in experienced hands after careful pre-operative correction of dehydration and anaemia.

"Parenteral diarrhoea" is given a definite place in the classification of infantile diarrhoea and vomiting in all paediatric textbooks, where it is usually stated that the gastro-intestinal symptoms are secondary to systemic or localized infection, and that they tend to clear up as soon as the parenteral cause is removed. The primary infection may be of virus, bacterial, or perhaps combined origin, and may be of surprisingly trivial nature. It is, however, well known that not all babies react thus to minor infections; and therefore, while accepting the role of the parenteral infection as an inciting agent in most of our cases, we feel that a greater tendency to respond to such stimuli by severe gastro-intestinal symptoms must be postulated in individual babies. Quite often the whole clinical picture is most suggestive of an upset caused by some "trigger" mechanism setting up the disproportionately violent reaction of diarrhoea and vomiting which eventually marches on its own way to a fatal outcome, regardless of the triviality of the first provoking factor. Here, certainly, death is due, not to infection, but to profound irreversible changes in the body chemistry.

Dehydration

The assessment of dehydration and degree of fluid loss is still based on subjective criteria and is often very difficult, especially in chubby, well-covered infants, in whom skin signs are absent or misleading. The need for a reliable laboratory or bedside test is great. Much excellent work has been done on the changes in body chemistry occurring in dehydration, in both adults and babies (Hoag and Marples, 1931; Aldridge, 1941). Most observers agree that the level of plasma chlorides and proteins in no way indicates the amount of fluid lost. The haematocrit and alkali-reserve determinations are considered more useful. In a few severely dehydrated infants in this series, all over 2 months of age, the haematocrit readings on admission ranged from 27 to 41 (average 36), obviously not confirming the clinical picture of severe fluid loss. When water balance had been restored, most of these infants were found to have a considerable degree of anaemia, which would account for the apparent absence of haemoconcentration. The accepted normal figure for the haematocrit in babies is 42, but Aldridge states that in infants of 2 to 8 months the normal reading is less than 38.

The low alkali reserve, ranging from 40 to 61.5 c.cm. (average 50.4 c.cm.), was more in keeping with the clinical condition of these infants. Unfortunately, the estimation of alkali reserve is time-consuming, and cannot easily be performed in small laboratories.

A raised blood urea was the most constant finding in our cases, the figures ranging from 50 to 112 mg. per 100 c.cm. (average 76 mg.), and corresponding fairly closely with the clinical assessment of dehydration in the individual cases.

PLASMA PROTEINS

The normal figures for plasma proteins in babies given in the literature vary widely. Hickmans, Finch, and Tonks (1943) give readings of 6 to 7.4 g. per 100 c.cm. for normal infants over 10 weeks of age. They quote Kylin (1932) for figures ranging from 4.6 to 6.5 g. for babies under 2 years of age, and Rennie (1935) from 6.04 to 8.0 g. per 100 c.cm. for babies of 3 to 23 months. The plasma protein levels found on admission in 7 of our severely dehydrated infants ranged from 3.06 to 6.44 g. (average 5.7 g.). The ages of these infants ranged from 2 to 8 months; and the average duration of diarrhoea before admission was 5 days, and of vomiting 3.9 days. Plasma protein levels were estimated in 4 other babies, 3 of them premature infants who, 1 to 2 days after intravenous therapy had been stopped, developed oedema while still apparently insufficiently hydrated. These values were: 4.7, 5.85, 5.7, and 4.3 g. per 100 c.cm., or an average of 5.14 g. Marked improvement and disappearance of the oedema followed the intravenous transfusion of half-strength serum in 2 cases, and of blood and half-strength serum in the other 2.

It is not unreasonable to assume that there exists in these infants some degree of protein deficiency, due mainly to restricted intake in their diluted feeds, and impeded digestion

and absorption of feeds, there may also be loss of proteins through the damaged capillaries of the intestinal wall. Recent work has shown that premature infants usually have a lower plasma protein level than full-term babies. Hickmans, Finch, and Tonks (1943) found readings of 3.7 to 5.4 g per 100 ccm in premature babies in the first four weeks of life. The deficiency may therefore be expected to be still more marked in premature infants with diarrhoea and vomiting, who probably also have a smaller store of proteins in their bodies.

Formerly, we had found the correction of fluid loss by crystalloid solutions very difficult in some cases, prematures, especially often became oedematous before being fully hydrated. The early administration of diluted serum or plasma has been of real assistance in overcoming this difficulty, and also in restoring and maintaining the circulation in badly shocked cases. We noted one other effect of the injected plasma—namely, an early reduction in the size and frequency of large watery stools.

DANGERS OF SERUM THERAPY

We wish to draw attention to the dangers of too enthusiastic serum therapy. During the course of intravenous therapy it was our custom to follow each vacoliter bottle of half strength serum or plasma by a bottle of half-strength Hartmann's (Ringer-lactate) solution—5% glucose. In 4 consecutive cases half-strength serum was infused continuously. Although the quantity of fluid given did not exceed the requirements for body weight ($2\frac{1}{2}$ oz per lb per day plus an allowance of 3 to 6% of body weight for dehydration), in less than 24 hours the children showed signs of respiratory embarrassment, marked cyanosis, rapid thready pulse, and anuria. No oedema was found. Two of these babies died of cardiac failure and 2 recovered after the administration of diuretics and continuous oxygen. The intravenous drip being discontinued. It seemed that in these small infants the continuous infusion of proteins caused the tissue fluids to be drawn into the blood stream in order to lower the raised osmotic pressure of the circulating blood, and there to be retained, thus causing circulatory embarrassment.

Hevl and Janeway (1942) state that 1 g of albumin, which is osmotically equivalent to 1.25 g of plasma protein, attracts, on an average, 18 ccm of fluid into the circulation in one hour. Thus the danger of giving large quantities of undiluted plasma intravenously to dehydrated infants is obvious. Normally, the total quantity of protein which we gave intravenously in the first 48 hours of treatment to a baby weighing 10 lb was approximately 15 g; the serum or plasma being diluted with Hartmann's solution. We are unable to say how much of this injected protein was actually metabolized by the body, but it is our impression that the plasma helped to restore the water balance more quickly and with greater safety and to maintain it until the infant was able to take full feeds.

LIVER CHANGES

We would like to make a plea for further research into the origin of the fatty liver so often found at necropsy on cases of protracted diarrhoea and vomiting. Macro and microscopic evidence of liver damage was found in 6 of our babies on whom post mortems were performed, in extreme degree in 2 of them. Lately, a good deal of work has been done on diets producing and preventing liver damage (Ravdin *et al* 1943; Himsforth and Givnn 1944). Although various other factors probably cause the initial toxic changes in the livers of babies suffering from diarrhoea and vomiting (e.g. infection) it seems to us that the extreme fatty infiltration often found after death may be at least partly due to protein starvation especially lack of some of the important amino acids. These children often live for weeks on diluted milk formulas, the digestion of which is further impeded by diarrhoea and persistent vomiting. We have often witnessed in these babies what in an adult case would have been called a death from liver insufficiency. This according to personal communication has also been the impression of other workers. Some of these infants did not appear at all cachectic even at necropsy, and yet the condition of their livers was clearly incompatible with life.

This applies equally to the plump, apparently slowly recovering babies, who when stricken down with a new infection very often have an alarmingly severe relapse, frequently fatal. The severity of the second attack is usually ascribed to a reinfection with a more virulent form of gastro enteritis. We feel that due attention should be paid to the possibility that these children, although outwardly in good condition, may not yet have repaired the liver damage caused by the first attack and possibly accentuated by weeks of careful but very deficient feeding. The inability of patients with damaged livers to stand up to even minor infections is well known, and this should be borne in mind before postulating increased virulence of the second attack.

Relapse

As has been said above there were 27 relapses in this series (19.3% of all cases) and 6 of these patients died. The relapses were commonly more severe than the primary attack. In 19 cases (70.4%) the relapse was preceded by pyrexia and clinical signs of parenteral infection.

Approximately half the infants (73) were nursed in cell wards, among these there were 6 relapses, or 8.2%, and 1 died. The remaining 67 infants were nursed in a 20-bedded "barrier" ward, with the same routine of management and treatment, here there were 21 relapses (31%), with 5 deaths. The highest relapse rate occurred during a period when the number of bottle babies in the barrier ward reached 16. Nursing in barrier wards, therefore however strictly the rules of bed isolation are observed, does not appear to be as effective as cell or single-bedded-ward nursing in the prevention of cross infection.

Haematology

In a number of cases, especially those in which a mastoiditis was suspected, total and differential white cell counts were made, but the results were inconclusive, this was possibly partly due to intensive sulphonamide therapy.

Haemoglobin estimations in some of the severely dehydrated infants were made on admission. Here again the findings were not helpful in the assessment of dehydration. Haemoglobin values (Sahli) ranged from 70 to 90% (average 80%), and did not confirm the clinical evidence of severe fluid loss and shock. In several of these cases an underlying, often severe anaemia became apparent when fluid loss had been corrected. Haemoglobin estimations in 30 infants who, though no longer dehydrated, were not making satisfactory progress showed values of 100% in only 2 cases. In the remaining 28, investigated between 5 and 37 days after admission, haemoglobin values ranged from 42 to 88% (average 60%). These low haemoglobin levels appeared to be due to a multiplicity of causes, singly or in combination: (1) Previous microcytic anaemia especially in the premature babies. (2) Effect of intensive sulphonamide therapy although this was usually well tolerated. (3) Insufficient intake of food during the illness and convalescence. (4) Insufficient absorption of food, vitamins, and administered iron due to changes in the intestinal mucosa even after cessation of diarrhoea. (5) Parenteral infection.

We found that the routine administration of iron in the form of a ferrous sulphate mixture combined with liberal allowances of vitamins did much to accelerate convalescence and recovery. Infants showing haemoglobin values below 60% were given transfusions of 200 to 300 ccm of blood often with dramatic improvement.

Treatment

This as previously described (Alexander and Eiser 1943), was based on the following principles.

1 The search for and elimination of, foci of parenteral infection. Sulphonamides chiefly sulphathiazole, were given in large doses (3 to 4 g daily for 5 to 7 days), and operative measures undertaken as required.

2 The adequate administration of fluids and food to meet the infant's daily requirements and to prevent the onset of dehydration and as early a return to full strength feeds as the infant would tolerate. On admission they were given half strength Hartmann's solution by mouth for 12 to 24 hours. If vomiting had ceased, dilute milk feeds 1/8 or 1/6 were then begun, and the strength of the feeds was gradually increased until the infant was taking a full strength milk feed usually in 4 to 7 days. If vomiting persisted all feeds were stopped and fluids were given parenterally. It

days. This period was decreased if doses of 25 to 50 mg. were given (Birnberg, Kurzrok, and Klor, 1940). Siegler and Silverstein (1940) inhibited lactation by giving total doses of 25 to 125 mg. of testosterone dipropionate in divided doses every 12 hours, with a total of three to five injections. Lass (1942) states that methyl testosterone in repeated doses of 25 mg. inhibits lactation in 48 hours; total dosage was from 250 to 350 mg. In 7 out of 25 cases methyl testosterone was effective on the first day.

A new synthetic oestrogen—octofollin or 2:4-di-(*p*-hydroxyphenyl)-3-ethyl hexane—has recently been used for the inhibition of lactation (Murphy, 1943). This, given over a period of four days in doses of 5 m.g. t.i.d., yields results similar to those obtained with stilboestrol.

From this discussion it is clear that hexoestrol dipropionate given parenterally is more effective for the inhibition of lactation than the other synthetic oestrogens and testosterone or its derivatives. With the possible exception of methyl testosterone none of these is effective in inhibiting lactation on the first day of treatment. The use of synthetic androgens in high dosage is ruled out on the grounds of expense.

Summary

A single intramuscular injection of 12.5 mg. of hexoestrol dipropionate inhibited lactation in 66% of a series of 44 mothers shortly after childbirth. When given within the first three days of delivery lactation did not occur, and there were no signs of breast engorgement or discomfort. Of the remaining 34% all but 2% ultimately responded to repeated injections. Only 18% required treatment for more than three days.

A further course of injections, given to suppress "secondary filling," was necessary in only 7% of the cases. This compares well with the figure of 25 to 45% for stilboestrol.

Hexoestrol dipropionate, given intramuscularly in one or two doses, was effective in suppressing lactation in five cases in which it had already been established.

Hexoestrol dipropionate given by mouth is not so satisfactory as when given by injection.

Literature on the inhibition of lactation by oestrogens and androgens is reviewed.

Thanks are due to the members of the resident medical staff of the Mothers' Hospital, Clapton, for their assistance and care in keeping records of the cases.

The 208th session of the Royal Medical Society of Edinburgh will open on Friday, Oct. 13, with an inaugural address by Lord Moran, P.R.C.P., on "The Anatomy of Courage." Other addresses will be given on Oct. 27, by Sir Joseph Barcroft, on "Problems in Foetal Life"; on Nov. 10, by Sir Alexander Fleming, on "Penicillin"; on Nov. 24, by Prof. J. H. Gaddum, on "The Discovery of New Remedies"; on Jan. 12, by Sir John Boyd Orr, on "The Future of Medicine"; on Jan. 26, by Lieut.-Gen. Sir Alexander Hood, on "The Army Medical Services in Peace and War"; on Feb. 2, by the Right Hon. Walter Elliot, on "Medicine and the State"; and on Feb. 16, by Col. J. C. Kimbrough, U.S. Army Medical Corps, on "Wounds of the Genito-urinary Tract in Modern Warfare."

FACTORS INFLUENCING DERMATITIS IN COAL-MINERS

BY

R. B. KNOWLES, M.D.

Many of the dermatoses to which miners are subject may occur in any person, whatever his trade, but some are directly or indirectly associated with the conditions under which these men work. The latter forms may be divided into two main groups: (I) those due, in the main, to trauma and infection, which might be called "the stigmata of miners"; (II) cases of dermatitis in the usually accepted sense, including occupational dermatitis.

Group I

The blue-black scar present on the skins of most miners is due to the fine particles of coal-dust which enter a wound at the time of injury. Callosities on the hands are common, and are to be seen across the heads of the metacarpals and on the inner side of the thumb, where the tools set up constant friction. The boots cause thickenings of the skin on the front and back of the ankle.

Bursae, true and false, play a part in the infections and injuries to which coal-miners are liable. False bursae may occur along the heads of the metacarpals, producing, when infected, the "beat-hand" of the miner. Bursae at the patella and olecranon may become the "beat-knee" and the "beat-elbow." Foreign bodies between the knee-pads and the skin sometimes help in the production of "beat-knee."

These infections are not likely to occur without some abrasion of the skin, which allows the entry of bacteria and provides a medium suitable for their growth. Various kinds of pyoderma may thus be produced either by staphylococci (boils, pustules, folliculitis, subcutaneous abscesses, and ulcers) or by streptococci (vesicles, bullae, impetigo, ecthyma, with lymphangitis and cellulitis, onychia, and whitlow). "Infected abrasions" are a very common condition among miners. Acid burns at the buttock, caused by the leakage of sulphuric acid from the lamp-battery, are also seen.

Group II

Clinically, acute cases are often eczematous, and chronic cases as a result of constant irritation and scratching, may become lichenified. Starting with erythema, the dermatitis may become vesicular, weeping, scaly, papular, pustular, and follicular. Occasionally there is fissuring of the palm. The chief symptoms are itching, soreness, and pain.

Most of these cases of dermatitis involve chiefly the hand and forearms, the feet and legs; but some begin on the trunk and others attack the trunk after starting elsewhere. Sometimes an intertrigo occurs in the axillae or groins, or between the toes. Encouraged by moisture, heat, and friction, streptococci produce this intertrigo of the skin; or it may be due to monilial infection and occur in the gluteal folds. In coal miners, intertrigo may also be found on the outside of the forearm and the inner part of the thigh, as the result of constant friction of the arm against the thigh when using pick and shovel.

An eczematous eruption in the external auditory meatus may be caused by particles of stone and coal falling into the ear which is uppermost when a collier is in the reclining position.

There are few miners who do not wear a belt, and friction between this and the skin may determine the onset of a dermatitis around the lower abdomen. Fungous infection of the feet has recently become prevalent, and its spread appears to be facilitated by pit-head baths. It is more common in the summer months, and occurs in three principal types: (a) Sudden wheal skin between and underneath the toes, especially in the four interdigital cleft. The infection may spread and produce pustules on the soles of the feet. (b) Superficial scaling of part of the hands or feet. (c) An eruption of deeply set vesicles on the soles of the feet: this is the most common type. The infection may also spread to the groins, to produce tinea cruris; the axillae, perineum, natal cleft, and thighs may be involved.

Improper treatment of wounds or skin lesions—e.g., by sulphur ointment, iodine, or antiseptics—may produce dermatitis.

Cleansing agents which are used to remove dirt and dust may be irritant to the skins of some miners, and a dermatitis may ensue, excessive use of soap may be the cause. Oil employed on coal cutting and boring machines may set up a dermatitis or paraffin used to remove oil may act similarly. Prolonged or repeated contact with oil may produce oil acne. Creosote dermatitis has been found among coal miners from handling creosoted props, the hands, wrists face, and neck are affected with a pustular eczema.

During the last few months I have visited nine pits in order to obtain information about the factors involved in the causation of dermatitis in coal miners. The conclusions reached are the result of personal observations and discussions with colliery officials and workmen, of experience in general practice in a mining community and of attending the skin department of the Chesterfield and North Derbyshire Royal Hospital.

These pits employ 7700 men and the number of cases of dermatitis certified over a period of two years was 56, a percentage of 0.70—the incidence in the separate pits varying from 0 to 1.8%. The accompanying table gives various details of

Table showing Details of 9 Pits including Incidence of Dermatitis

Pit	Depth (yards)	Month	Dry bulb Temp (°F)	Wet bulb Temp (°F)	Relative Humidity %	Dermatitis in 2 Years	Height of Coal Face	No. of Men Employed	Distance Coal Face from Shaft (in feet)	Pit head Baths	Fungus Infection of Feet Reported
A	155	Dec	60	55	92	0.6	50	300	15	Yes	No
B	265		70	69	94	0.8	40	700	15	Yes	No
C	310		63	60	95	0.3	40	1600	15	Yes	No
D	110		70	69	92	0.17	50	600	15	Yes	No
E	170	Jan	58	57	92	0.2	50	500	15	Yes	No
F	720		51	71	66	1.8	40	100	15	Yes	No
G	700	May	71	61	85	0.6	40	650	15	Yes	Yes
H	640		62	57	92	0.83	50	1200	15	Yes	Yes
I	800		74	70	95	0.11	40	850	15	Yes	No

the pits visited. The hygrometer readings are those in the return airway after the air has circulated along the coal face.

The pits vary in depth and in working conditions. D and E are very wet, the others are on the whole dry pits, water being found only in certain districts in C and H. F is a flat deep pit, and the coal face is two miles from the shaft. All except three have pit head baths, and the incidence of dermatitis in these three is not high. An outstanding point is that in F the incidence of dermatitis is more than twice as high as that in any of the other pits—it is significant that it is the hottest pit.

Aetiology

The chief factors influencing the nature and cause of dermatitis in coal miners are:

1 *Factors due to Pit Conditions*—(a) The vent lat on of the pit temperature, humidity, height of coal face, distance of coal face from shaft. (b) The presence of water and the substances dissolved in it. (c) The quantity, quality, and state of subdivision of dusts and the effect of machinery on these.

2 *Factors due to the Mental and Physical Constitution of the Workmen*—(a) Behaviour in relation to trauma and infection. (b) The presence of skin conditions—seborrhoea, hyperidrosis, ichthyosis—which may predispose to dermatitis.

3 *Friction between skin surfaces or between clothes and the skin.*

4 *The use and abuse of cleansing agents and popular skin applications in general.*

Pit Conditions

Ventilation—Of paramount importance is the ventilation of the pit on this depend the temperature and the amount of sweating. Dermatitis appears to be more common in deep hot pits where sweating is profuse and the air current does not evaporate the sweat from the body.

Humidity—The factor next in importance is the humidity of the atmosphere. The amount of sweating depends to some extent on this, for at a given temperature, the higher the relative humidity of the atmosphere the less will be the evaporation of sweat. A man's capacity for work is greatly impaired when

the wet bulb temperature exceeds 82° F, and even at a wet-bulb temperature of 72° F inconvenience is felt unless only light clothing is worn. It may be possible to do a fair amount of work at wet bulb temperatures above 82° F if air at a good velocity is kept blowing over the exposed surface of the miner but the limit is 85° F. It seems that the dry-bulb temperature is of secondary importance, as a case is recorded in which the man—working devoid of clothing—experienced little inconvenience in a temperature of 95° F dry bulb and 74° F wet bulb (Penman and Penman, 1927).

Height and Distance of Coal Face—Two other factors are the height of the coal face and the roof in general, and the distance of the coal face from the shaft. A shallow coal face makes the working conditions more difficult, walking in a pit the roof of which is low produces more sweating and increases the amount of friction on the body surface. The temperature at the coal face depends to some extent on the distance of the latter from the shaft.

Presence of Water—Pit water, and mineral salts and organic matter dissolved in it, play a part in the production of some cases of dermatitis. Pits D and E are very wet, but have a low incidence of dermatitis and a high one of fibrositis and myositis in these pits the men are exposed to water under foot and from the roof. But the pits are shallow, and the water is mainly from the surface and has not percolated through much depth of soil and rock. On the other hand, water in a deep pit has a higher concentration of salts and seems to be more irritant. In pit H men had more irritation and smarting of the skin when working in a wet part.

Dusts—Dust is produced in large quantities in coal mines—probably more so since the introduction of machinery. Limestone dust is also strewn in the roadways. In the mines, dust collects on the face, trunk, hands, knees, ankles, and between the toes. Friction between skin surfaces or between clothes and the skin rubs dust in—it is not usual for dermatitis in miners to begin on the trunk above the line of the belt. More often it begins on the hands and forearms, or legs and feet and particularly at the boot top level, or, if on the trunk, in the region where the trousers or shorts are held in contact with the skin. In these places there is friction. During the exit from the pit all these factors—sweating, dust, and friction—are in operation. The quantity of dust can be reduced by having a fine spray of water operating where dust is produced in large quantities (coal-cutting machines, borers, and at the loader end).

The Constitutional Factor

Since the majority of coal-miners are not prone to occupational dermatitis, some other causal factor must be inherent in the sufferers themselves. Intelligence, behaviour, general health, and the texture and natural qualities of the skin may determine whether a dermatitis occurs, and, if it does, may modify the type of dermatitis produced. Men with thick, dark oily skins are, as a rule, less susceptible than those with fair, thin dry skins. Those with relatively hairless skins are less liable to folliculitis from oils and grease than those with hairy arms and legs. Ichthyosis predisposes to dermatitis. A seborrhoeic skin is greatly affected by sweating and seborrhoeic dermatitis is not uncommon among miners. Hyperidrosis may be a potent factor in the causation of dermatitis.

In other cases dermatitis is caused by cleansing agents or applications of ointments or antiseptics to some existing skin lesion.

Conclusion

Dermatitis in coal miners then is not due to any single cause—it is the summation effect of many factors some of which are provided by the conditions of work and others by the constitutional make up of the men. The prophylaxis of dermatitis in coal miners depends on avoiding the causes so far as is possible. The chief points in prophylaxis are:

- 1 Adequate ventilation of the pit is essential.
- 2 The quantity of dust must be reduced to a minimum.
- 3 Water, if possible, ought to be pumped away.
- 4 Education of the miner by

(a) Notices posted at the pit telling him to report any suspected dermatitis at its onset, (b) instruction of ambulance attendants on how to treat such cases—e.g., application of protective lotion,

(c) warnings of the possible effects of unsuitable cleansing agents and home remedies (good soaps, vegetable oils, and liquid paraffin allowed); (d) emphasis on the advantages of cleanliness.

5. Selection of suitable personnel for work in the pit.

6. Application of protective substances to the skin.

7. Warnings of the increased risks of working when ill or insufficiently recovered from illness.

8. Prevention of fungus infection of the feet—a difficult matter:

(a) New workers should be examined before they are admitted to the baths. (b) To prevent contact between the feet and the bath floors, slippers should be worn and sterilization of these be periodically carried out. (c) Infected men should have separate baths.

My thanks are due to the University of Sheffield for permission to publish this article, which is an abstract of a thesis; to the managements of the collieries I visited; and to Dr. Rupert Hallam, dermatologist to the Chesterfield and North Derbyshire Royal Hospital, for his helpful suggestions.

INTRAVENOUS ANAESTHESIA

CONTINUOUS POSITIVE-PRESSURE DRIP SALINE WITH INTERMITTENT PENTOTHAL

BY

W. M. MAIDLOW, M.R.C.S., D.A.

Major, R.A.M.C.

Many articles have recently appeared on pentothal anaesthesia with drip-feed continuous saline, and each of the various methods has its advantages and disadvantages.

Criticisms of Previously Described Methods

Drs. Roberts and Sellick (1944) have answered Mr. O'Connor (1944) satisfactorily, by stressing the fact that the metal stand used in the gravity technique is both cumbersome and often in the way of the surgeon or assistant. A further disadvantage of this method is seen when the operating table has to be moved during the operation—as, for example, during a meniscectomy, when the surgeon, having been operating with the leg bent over the end of the table and the light shining over his shoulder into the joint, starts to sew up with the leg straight and the light directly overhead. This entails moving the whole table some distance, so that the drip has to be moved also. Care has to be taken not to dislodge the needle or connexions as the tubing sways, the container has to be steadied in case it becomes unhooked or is broken, and at the same time the anaesthetic machine, if in use, has to be moved also.

Dr. Griffin (1944) overcomes this difficulty to a certain extent by affixing the drip-container to a bar on the Boyle's table model. This type of machine is, however, by no means universal, and I for one would hesitate to make such an alteration to a McKesson machine or to my own portable apparatus.

Mr. O'Connor had criticized the apparatus described by Drs. Roberts and Sellick (1943) by suggesting that leakage of blood may occur back from the vein during intervals of injection or if the pressure in the saline bottle should drop. Drs. Roberts and Sellick counter this criticism by saying that a clip can be fixed distal to the bellows to prevent leakage of blood back. They point out that the ideal method is to use a flow of oxygen to produce the necessary pressure. Besides being wasteful, I cannot quite see why a minor explosion does not occur in the saline bottle when the tubing is pinched to admit the pentothal, unless the oxygen supply is turned off during this procedure, thus adding an extra manipulation. This could, of course, be avoided by fitting an automatic mercury manometer or blow-off valve; but this only adds further complications and, to my mind, disadvantages. It is my intention to describe a simple method that will obviate these difficulties, still employing the bellows method of producing pressure for the drip.

Having used the gravity method for a considerable time, I decided to try the positive-pressure method, when I was

confronted with the difficulty of having no stand on which to hang my saline reservoir, and by the fact that I had been anaesthetizing for a fairly large series of meniscectomies (sometimes 6 in a morning) and becoming more and more tired of lugging a heavy metal stand to different positions. Also people in the theatre frequently tripped over the metal base. I had a mental picture of the surgeon one day stepping back and losing both his balance and his dignity.

There are a number of disadvantages in using the technique described by Drs. Roberts and Sellick.

1. Constant pricking of the tubing raises the question of sterilizing the puncture site at every injection, with consequent delay at a time when the patient requires a further dose immediately.

2. The need to pinch the tubing to avoid backwash, thereby possibly obscuring the drip chamber, means that the anaesthetist's hand is taken from the patient's jaw and his attention from the general condition.

3. Towels that may be in the vicinity of the operation have to be touched, and are perhaps disarranged, which may interfere with the surgeon or assistant.

4. The question where to place the syringe during intervals between injecting and the question of the sterility of the needle.

5. The eventual destruction of the rubber tubing (it is better to have thin-walled tubing, as it is lighter on the needle), with consequent leakage, which seems to occur most often at the start of a new case, thus not setting out with a 100% efficient system.

The aspiration indicator described by Drs. Roberts and Sellick is a most useful adjunct after induction of the patient in his bed or on a stretcher; with it we can be quite sure the needle is in the vein when making the puncture on the operating table. I have, however, made it a rule to avoid all extra glass tubes, indicators, adapters, and wire bindings which perish the tubing, so as to minimize leakages from the system.

Regarding Dr. J. L. Griffin's method, the main disadvantages seem to be:

1. The apparatus in cumbersome to sterilize.

2. The risk of breakage opens up the question of expense and possible difficulty in replacing the containers immediately.

3. The length of tubing necessary.

4. The U-tube method, with two containers and one drip chamber, makes it difficult to estimate the exact dose that is required immediately. There must be some delay while the saline in the tube distal to the drip is run through, and the surgeon does not wait before exciting any strong stimulus, which may not have been adequately anticipated. Again, the patient, having been placed at a required depth, will proceed to become a certain degree deeper when the saline is readmitted, from the pentothal still remaining in the tubing. This allows an error to occur in the estimation of dosage. I note, however, that Dr. Griffin uses 2% solution and anaesthetics, and tubing of very narrow bore; but the margin of error still remains, and can be entirely overcome by the method described below.

An Effective and Simple Method

To overcome the above disadvantages I now use a three-way tap, which is situated close to a needle of medium length to facilitate removal of the syringe. One hand turns the tap, which is easily found even if covered with towels, and the same hand injects the pentothal, which is therefore admitted almost at the site of venepuncture, thus entirely overcoming all question of dead space. At the same time the flow of saline automatically ceases, and there can be no backwash or leakage up any tubes. The third arm of the tap runs to a reserve supply of pentothal in a gallipot slung in a ring on a metal stand. This stand is clamped to the arm-rest or a table, if the leg is being used, and consists of an upright metal bar about 6 in. high, on top of which is a platform holding the metal clip from the box in which all Record syringes are supplied. The 20-cm. syringe rests in this, and is quite secure and out of the surgeon's way. The syringe here comes easily to the hand of the anaesthetist, who remains seated at the head. About 6 in. of narrow-bore thin-walled tubing runs from an adapter on the syringe to one arm of the three-way tap. Another arm carries the tubing from the drip bulb and bottle; a metal sinker holds the tubing in the reserve pentothal supply.

There is one slight theoretical disadvantage when using the positive-pressure technique—namely, on turning the tap to inject pentothal the drip saline continues unless the clip proximal

to the drip is turned off. This, however, requires an extra movement of the hand, with consequent delay. In practice I have never seen the drip chamber fill up during this procedure—in fact, I keep the meniscus of saline right at the bottom of the drip chamber all the time, and see no use for the employment of a side-tube and clip. Here I must admit that the turning of the three-way tap does in one motion cut off the drip in the gravity method. I insert an air filter similar to those found on the Bristol blood sets, fitted between the bellows and the saline bottle. This may hold up certain bacteria which might otherwise reach the saline.

FIG. 1

The great advantage of this method is that it is only necessary to sterilize the metal rods which pierce the rubber bung (which is encased in sterilized "cellophane"), the drip chamber, and tubing. I have these autoclaved after every operation session in which they have been used. All I need to change between cases is the needle. Bottles containing sterile normal saline are stored ready.

With this technique an accurate dose can be administered immediately with the least amount of effort or movement by the anaesthetist, and if the operating table has to be moved, all that he need move is the table on which the bottle stands, which may also be the anaesthetic machine in the case of Boyle's table model. It is important to ensure that the rubber bung, the rods piercing it, and all joints are airtight.

Strength of Solutions Used.—I see no advantage in inducing with one strength—say, 5%—and continuing with 2½%, which, as Drs. Robert and Sellick point out, only confuses the estimation of dosage. I use 5% all the time for fit cases, and 2½% all the time for weaker or shocked patients, or for longer cases with a minimum of trauma—as, for example, in the application of a plaster-of-Paris spica.

Use of Analeptics.—I consider the use of analeptics during the operation, besides predisposing towards post-operative vomiting, an admission of lack of faith in the technique: the maintenance of blood pressure, amplitude of respiration, and oxygenation must be ensured by an adequate airway and the use of oxygen and/or supplementary nitrous oxide (see below).

Technique.—In practice, pressure is raised, the bellows clip tightened, and saline run through to the three-way tap; the flow is then stopped, pentothal is run through from the syringe to the three-way tap, and the syringe is refilled from the reservoir. In the Army it has been my practice to induce all patients on the operating table with their arm outstretched and bandaged down in position on a pillow on the arm-rest. Ill patients or those with severe painful fractures are induced in their beds, the syringe being removed and a fresh puncture made when they are in position. Here the aspiration indicator would be useful, but without proper adapters I found that glass tubing with two rubber joints very quickly became leaky. As soon as induction is complete and the patient is at a depth suitable for the proposed operation the syringe is removed, the three-way adapter connected to the needle, and the saline drip begun. Pentothal is added at fairly frequent intervals at the start, in 1 to 2 c.cm. doses and, later on, at much longer intervals.

Uses and Limitations of Intermittent Pentothal and Importance of Supplementary Anaesthesia

Concerning the use of oxygen and supplementary anaesthesia, oxygen alone, except as a resuscitative measure, is not satisfactory, as very much larger doses of pentothal are required, and I aim at keeping the total dosage of that drug below 2 g. If the operation is likely to be long I always use $N_2O + O_2$ to supplement and cut down the dosage of pentothal. I do not start supplementary anaesthesia until the operation is well under way—say, 15 minutes—and the patient is well settled; then I add $N_2O + O_2$, preferably with partial rebreathing and not closed-circuit technique, and add just enough pentothal to obtain adequate relaxation and quiet breathing, and to cut out the shock stimuli from the surgical trauma. This enables the patient to move his "bases" adequately, and is of great benefit in the post-operative condition, especially of Army patients undergoing herniorrhaphy, in which "chests" are so common after all forms of anaesthesia.

I consider operations of longer duration than 1½ hours generally to be unsuitable for pentothal, as are also those in which there is considerable surgical trauma and strong stimuli are evoked which would necessitate larger doses of the drug, causing it to produce its cumulative effects and give it the status of the long-acting barbiturates with their marked post-operative depression. I noticed this particularly in three cases recently—viz., nephrectomy (heavy stimuli and degree of relaxation required for exposure and delivery); colporrhaphy (duration of operation and surgical stimuli); colostomy (weakened condition of patient).

In my experience this form of anaesthesia is also unsuitable for abdominal explorations and for appendicectomies in robust individuals. Here a spinal block, regional block, or cyclopropane is the best method of achieving the relaxation required. It is highly suitable for all orthopaedic cases of less than 1½ hours' duration—skin grafts, nerve explorations, and tendon suture operations, herniorrhaphies, Trendelenburg's operation for varicose veins, traumatic surgery, lacerations of scalp, and possibly for women and young adult "abdominals."

I have used intermittent pentothal with a saline or glucose drip for very long operations such as cholecystectomy, gastrectomy, anastomotic operations, and Gallie's herniorrhaphies performed under spinal analgesia. This may stimulate reprisals, but I would stress the fact that in these cases it is used in absolutely minimal doses simply to keep the patient asleep where control by $N_2O + O_2$ may be difficult, or where premedication is wearing off and cyclopropane is contraindicated owing to its depressant respiratory action. For craniotomies also it may be useful when avertin is wearing off and lipid-soluble supplements to $N_2O + O_2$ are inadvisable.

Figs. 1 and 2 are diagrams of this apparatus, which has proved efficient and simple, and for which I claim no originality, since it has been culled from the numerous and varied ideas of other authors writing on the subject.

SYMPATHETIC BLOCK

PROPOSED THERAPY IN TRAUMATIC SHOCK

BY

D. ENGEL, M.D., F.R.C.S.Ed.

Medical Superintendent, Staincliffe County Hospital, Dewsbury

The purpose of this paper is to draw practical conclusions from recent experiments (Engel and Forrai, 1943; Engel, 1943) and to propose regional sympathetic block as a preventive and curative method in cases of extensive crush injuries. Though my proposal is based on animal experiments there is enough clinical evidence to support my views.

The result of the experimental work can briefly be summarized as follows: In "traumatic shock" the rate of filtration through the capillaries in tissue adjacent to trauma, and probably also in the traumatized tissue itself, is greatly increased in the first 1 to 5 hours following trauma, and reduced afterwards. The increased rate of filtration, suggesting increased capillary permeability, is thus restricted to the traumatized area and is not generalized over the whole body. It was further shown that by regional sympathectomy it is possible to reduce considerably the increased rate of filtration caused by trauma.

These results were obtained by a new method consisting of a constant intravenous infusion of a dye and a simultaneous perfusion of the two knee-joints with Ringer solution under various conditions. The dye appearing in the perfusate passes through the "articular barrier"—i.e., the capillary endothelium, the synovial membrane, and the thin layer of tissue or space between the two.

The practical significance of these experiments is that if it is true that capillary permeability is one of the most important initiating factors in the development of "shock," then every procedure that is capable of reducing capillary permeability is bound to have a beneficial effect.

Technique

The simplest and most practical way of paralysing sympathetic action and thus reducing capillary permeability in the traumatized area without damaging the patient is the paravertebral infiltration of the regional ganglia with novocain. This should be carried out as soon as possible—in any case, within the first 1 to 3 hours after trauma. We have seen that the period of increased capillary permeability lasts only 1 to 5 hours, to be followed by a period of decreased permeability. No effect can therefore be expected after 5 hours. These results were obtained in the cat; it is therefore possible that the time limits mentioned do not apply exactly to human beings.

An anæsthetic of short effect, preferably novocain, should be used, because the second period of decreased permeability does not develop in the sympathectomized limb, and it is very likely that a prolonged sympathetic block may have a similar effect to that of sympathectomy and fail its purpose. If the lower extremity is crushed the first to fourth lumbar and the first sacral ganglia, if the upper extremity is involved then the stellate and the first and second thoracic ganglia, have to be injected. About the technique of the sympathetic block nothing more need be said; it is standard method.

Observations in the Literature

I have no personal experience of sympathetic block as a prophylactic or curative method against shock. There are, however, numerous clinical observations which support the usefulness of this method.

Several authors (Philipowicz, 1942, and others) reported on the excellent results obtained by sympathectomy in cases of frostbite. The inflammatory exudate and odour diminish immediately after operation, the moist gangrene becomes dry, and the demarcation is accelerated.

It is also a well-known fact that abdominal operations performed under lumbar or splanchnic anaesthesia cause much less shock than those under general anaesthesia, in spite of the falling blood pressure, which would be expected to favour the development of shock. The fact that shock does not develop so readily under lumbar and splanchnic anaesthesia is possibly due to the reduced capillary permeability in the abdominal tissues, temporarily excluded from sympathetic innervation.

The idea that the sympathetic has an influence on the development of traumatic shock is not new. The literature on the subject has been reviewed up to 1941 by Harkins (1941). We shall therefore consider here only the most important papers which have some bearing on capillary permeability. It was Cannon (1923) who first suggested that the hyperactivity of the sympathetico-adrenal system, excited by sensory-nerve impulses, is an important factor in traumatic shock. This theory was based partly on clinical observation, partly on experiments showing that continuous sympathetic stimulation or hyperadrenalinaemia led to a decreased blood volume and low blood pressure. It was assumed that a prolonged arteriolar constriction resulted in a capillary anoxaemia with consequently increased permeability, fluid loss, and final shock.

The effect of adrenaline in various concentrations on blood pressure, blood volume, haemoglobin concentration, etc., was examined by several authors. Freeman and co-workers (1936, 1941) produced a prolonged hyperactivity of the sympathetic nervous system by injecting adrenaline in physiological doses or by spontaneous emotional activity of the pseudodffective state. Both procedures resulted in a decreased circulating blood volume. This decrease did not occur when the vasoconstrictor action of the sympathetic was inhibited by ergotamine, or when the emotional hyperactivity of the pseudodffective state was produced in a totally sympathectomized cat. Freedman and Kabat (1940) could not confirm all the results and conclusions of Freeman; they did not, however, rule out the possibility that sympathetic hyperactivity may play a part in shock following haemorrhage and fluid loss.

The experiments of Slome and O'Shaughnessy (1938), as well as those of Lorber *et al.*, emphasize the importance of the nervous factor in the development of traumatic shock. Either they severed the limb from its nervous connexions (nerve section, spinal section, spinal-cord destruction, spinal anaesthesia) or they severed the limb from everything except its peripheral nerves. The significance of the nervous "factor" became evident from both these series of experiments, but neither has taken the fact into consideration that the three spinal nerves of the lower limb—the femoral, sciatic, and obturator nerves—carry the bulk of its sympathetic nerve supply. It is therefore not clear from these experiments how much of the recorded effect was due to sympathetic action or inaction.

Lena Stern (1942) recently reported good results by stimulating the sympathetic centres and lowering the parasympathetic tone. She injected potassium phosphate direct into the cerebro-spinal canal in all those cases in which a fall of blood pressure, a lowering of cardiac activity and respiration, etc., were manifest. Stern saw all these signs disappear, in men and in experimental animals, by her method. Her treatment is based on the view that "the sympathetic and parasympathetic nervous centres play the most important part in the production of shock." She warns against the use of potassium phosphate "in cases in which there is increased excitability of the sympathetic nervous centres, such as sometimes occurs in the first stage of shock"; potassium phosphate should be given only in the second stage.

It is not possible fully to co-ordinate the experimental and clinical results of Stern with my own; the following suggestion seems, however, to be justified. The first period of sympathetic stimulation of Stern is very probably identical with my first period of increased permeability, and her second period of sympathetic depression identical with my second period of decreased permeability. Should this assumption be correct our two ways of therapeutic approach would prove to be complementary: the sympathetic block would be indicated during the first period, so as to prevent plasmorrhoea through the capillaries and thus the development of the second phase. Should the second phase develop in spite of the sympathetic block, or should the patient come under treatment at this late stage, an intrathecal injection of potassium phosphate may be indicated provided that further observations should confirm Stern's report.

Another explanation for the apparent discrepancy between Stern's results and mine might be the interesting fact described in earlier papers of Stern, that there is an "antagonism between the central and peripheral parts of the central nervous system as regards their reaction to the same substance." It is therefore possible that a central, intraventricular stimulation of the

sympathetic is equivalent in its physiological effect to a peripheral inhibition. Further experiments will be required to solve this question.

Conclusion

This short review of the literature and my own experiments should suffice to indicate the significance of the sympathetic nervous system in shock. It is the purpose of this article to lay down principles which, if put into practice, may prove to be of value. It is not advocated that other methods which have proved, so far, to be indispensable (blood transfusion, etc.) should be neglected. The combination of both should be tried in suitable cases. They are certainly harmless, and may be of great advantage to the patient. Only clinical experience will enable us to accept or reject these recommendations.

Medical Memoranda

Suppurative Pylephlebitis

This case is reported for its clinical rather than its pathological interest.

CASE HISTORY

A woman aged 60 was admitted after the gradual onset of vague lumbar pain and nausea. She had no urinary or bowel symptoms, no shoulder pain or vomiting. She was obese and had always had a diffuse brown pigmentation, especially on the arms and legs. Her temperature was 99° and pulse 70. Her abdomen was soft nowhere tender and her liver was only just palpable. Within a few hours she lost both pain and nausea, but the next morning had a rigor. From then on she had a total of 31 rigors at intervals of 1 to 12 days. The temperature with a rigor varied from 100.4° to 105°, between rigors it swung between 97° and 101°. There was no rhythm or regularity either in the frequency of the rigors or in the daily temperature variation.

Apart from the rigors she had no other symptoms or signs. In fact, at the seventh week, after her longest interval free from rigors, she seemed so well that she was sent home, but she soon had another rigor and came back. After ten weeks she had a slight pain low in the left posterior axillary line, and we heard a pleural rub. This was replaced by a patch of dullness to percussion, but paracentesis yielded nothing and we thought that the dullness gradually disappeared. There followed another long period in which she felt perfectly well and ate heartily, this was the perplexing part of the picture. Then one evening in her eighteenth week she had a sudden attack of violent coughing produced some foul green brown mucus, became rapidly very ill and died.

Investigations.—Blood.—1st week. Hb 83%, leucocytes, 17,000—polys 83%, lymphs 13%, monos 3%, plasma chloride 608 mg per 100 ccm, culture sterile agglutination negative for typhoid, Salmonella, dysentery groups, and abortus. 2nd week. Culture—no pathogen. 4th week. Hb 85%, leucocytes, 12,000—polys 74%, lymphs 22%, monos 3%, culture sterile, agglutination negative for typhoid group and abortus, staphylococcal antileucocidin index, 0.16 K (upper limit of normal). 6th week. Leucocytes, 18,000. 9th week. Leucocytes 54,000—polys 93%, lymphs 4%, monos 3%, culture sterile, W.R. negative, Kahn negative, urea 70 mg/100 ccm. Urine.—1st week. N.A.D., distasteful index 5. 2nd week. N.A.D. Faeces.—1st week. Culture—no pathogen. 9th week. Culture—no pathogen. Sputum.—3rd week. Atypical haemolytic streptococci. 18th week. Offensive green brown fluid, mixed bacteria mostly *Staph. aureus*. X-ray.—Gall bladder. No opaque calculi. Graham's test suggestive of pathological change. Chest. 2nd week—N.A.D. 6th week—N.A.D. 11th week—left basal pleural effusion, left diaphragmatic outline not seen, right diaphragm normal.

Post mortem. Emurction.—Pus in lower half of left pleural cavity, loculated by light adhesions communicating at one place, through lung with bronchi. Multiple small abscesses in liver, pus in terminal section of portal vein. Microscopy showed suppurative pylephlebitis with pus in portal veins, in many systems replacing wall and tissue round veins. All other organs including appendix, healthy, except the gall bladder, which was fibrosed and contained stones. We could not see how infection reached the left pleura—probably directly through lymphatic channels, but it is curious that the right side was unaffected. No local track was detectable. It seemed unlikely to be blood borne for it was the sole distant focus.

COMMENT

A case of irregular pyrexia with frequent rigors and a mild leucocytosis throughout. The pigmentation reminded us of

Addison's disease, but this was quickly dismissed. Typhoid, abortus, and glandular fevers were not seriously considered because of the leucocytic activity, the first two were, in any case, eliminated by agglutination. A kidney abscess was eliminated, so far as was possible, by investigations. Eventually there remained the possibility of a chronic septicaemia. Three blood cultures were sterile, this however, did not rule out a portal pyaemia. Mr. Henry Thompson was consulted, and the possibility of this and of a Charcot's biliary fever was discussed. Then when pus burst into the left bronchi, we thought we might have missed a latent pulmonary or subphrenic abscess. Yet we were not greatly surprised at necropsy to find pylephlebitis, this insidious disease, whose nature remains cryptic for so long, could at the best have only been guessed at, and was.

Unusual features of this case were the large number of rigors, the fact that, throughout, these were the sole clinical manifestation (the only localizing signs were those of the pleural complication), the uncommon primary focus and the unique termination.

I wish to thank Dr. Julius Burnford for his help and for permission to publish this.

P. MACDONALD TOW, M.R.C.S., L.R.C.P.

Broad Ligament Cyst in a Strangulated Hernia

Past records have shown that an inguinal hernia may contain a variety of different organs, both normal and pathological, but I think that this case is unusual enough to merit publication.

CASE RECORD

The patient, a widow aged 43, was first seen on May 5 1944. She said that she had had a hernia for twelve months, but this had always been reducible and symptomless. At 5 p.m. on that day, while chopping wood she had a sudden severe abdominal pain and repeated vomiting, and the hernia became irreducible. On admission her temperature was 101.2° and pulse 112, and she had a right irreducible inguinal hernia, but a cough impulse was present. A cystic abdominal tumour was noticed, arising from the pelvis and extending about two inches above the umbilicus. There were no signs of pregnancy, and her periods were normal. The passage of a catheter did not reduce the swelling. The patient stated that this swelling appeared to fluctuate in size from time to time.

At 10 p.m. operation was performed, and a sac of an inguinal hernia was dissected out. On opening the sac a fibrous mass the size of a pigeon's egg was delivered, attached to a cystic swelling which was not bowel or bladder. This in turn was opened, and a large quantity of clear yellow fluid escaped. Five pints of fluid were aspirated, and the abdominal swelling dramatically diminished. The cyst was closed by a purse string suture, and the fibrous mass, presumed to be necrotic ovary, was sent for section. (On microscopy, this later proved to consist of lymphoid tissue, with numerous foreign body giant cells and granulation tissue, but no evidence of ovarian tissue.) The patient's condition did not justify laparotomy at this stage so the hernia was repaired in the usual way.

On May 8 the temperature rose to 103° and thereafter was swinging there was also some inflammation of the wound. Sulphathiazole (23 g) was given. On May 14 she developed diarrhoea, which was presumed to be due to infection of the cyst.

On May 16 laparotomy was performed through a right paramedian incision. Intestines were packed off, and a large cyst was partly delivered into the wound, a purse string suture was applied, and a French's needle was inserted. Four pints of thick pus were aspirated. The hole in the cyst was then closed. The cyst was then dissected out with difficulty owing to dense adhesions, and was found to be retroperitoneal and to extend from the loin to the pelvis. The upper pole was in relation to the kidney, but not adherent to it. The lower pole was within the right broad ligament. The uterus and both Fallopian tubes and ovaries were normal. The cyst was removed and a drainage tube was inserted through a stab wound in the loin and another through the lower end of the incision draining the pouch of Douglas. During the operation one pint of blood was given intravenously, and, on account of the possibility of general peritonitis and paralytic ileus, intravenous glucose-saline was given post-operatively for 48 hours, and fluids by mouth restricted to sips. Sulphathiazole (27 g) was given prophylactically. The tube in the loin was removed after 48 hours, and that draining the pouch of Douglas on the fourth day. Slight pyrexia persisted for 18 days, but the patient made an uninterrupted recovery.

COMMENT

It was concluded that this was a cyst of the broad ligament, a lobule of which had become strangulated in the inguinal hernia. Section of the cyst wall showed it to be composed of acute inflammatory tissue, lymphoid and fibrous tissue; the epithelial lining had been destroyed by the acute inflammatory changes.

My thanks are due to Dr. C. H. Laver for his permission to record this case, and for his helpful criticism of the account.

Redhill.

House-surgeon, East Surrey Hospital.

Reviews

MEDICAL SERVICES IN EIRE

The State of Medicine in Ireland. By W. R. F. Collis, M.D., F.R.C.P., F.R.C.P.I., D.P.H. Carmichael Prize Essay. (Pp. 70. 2s. 6d.) Dublin: The Parkside Press, Ltd. 1943.

Prize essays are often of academic interest only and, soon forgotten, but this one deserves a happier fate. It calls for the serious attention of the Government and medical profession of Eire. It is a restrained but severe criticism of the lay-out of the services of that country. Dr. Collis sadly confesses that the medical reforms which were hoped for when Eire became a sovereign State have not materialized. In his preface the author emphasizes two premisses upon which the work is built. The first is that a point has been reached in the general conception of health policy which insists on a new stocktaking. He deals with the present situation in Great Britain, and says, "If medicine in England needs reorganization, medicine in Ireland needs it more." And this is amply borne out by his facts. Secondly, there is an "atmosphere of mutual distrust between the profession and the Department of Local Government and Public Health which, if allowed to develop further, will gravely compromise the health of the people of Eire." We think that this also is fully substantiated.

National Health Insurance in Eire provides no medical benefit. The insured population has to depend on the Dispensary system, which is still on "the pauper basis." The faults of this system have been exposed over and over again, and never more trenchantly than by Surg-Gen. Evatt, who, as a special commissioner of the B.M.J., visited Ireland in 1902. "Any treatment an insured sick person obtains is on the pauper basis through the dispensary doctor or by charity in a voluntary hospital. The idea that this is degrading to the honest citizen . . . has not yet penetrated the mass mind of society here."

Dublin has more small general and special hospitals than any other city of its size, with the inevitable out-patient abuse. There are State county hospitals which, in essence, are workhouse hospitals, though separated from the workhouse itself. The staffing of many has been improved. The windfall that the voluntary hospitals got from the Hospital Sweepstakes has been a doubtful advantage from the national point of view, because it gave an excuse for delay in dealing with the national problem. Dr. Collis describes the struggle among the hospitals for the millions of pounds which accumulated, and of which a large amount still remains undistributed. A Hospital Commission was appointed, but, its function being only advisory, the onus of implementing its recommendations was on the Ministry, whose attitude is apparently still governed by the Poor Law conception. Recommendations in favour of setting aside a large sum for the greatly neglected subject of research were ignored. The sweepstakes came to an end with the outbreak of war without any attempt to tackle national medical reconstruction. Dr. Collis believes that the profession has lost faith in the power or the will of the Department to plan a real medical service for the country, and says it "has no interest in preventive or social medicine."

Proposals are made for the future, and he hopes that the profession will itself put up a plan for co-ordination of the medical services, though he is very doubtful whether, without a considerable stirring of public opinion, the Department will take any action. He suggests a National Board of Health, with the Minister of Health and Social Welfare as president, having representatives of every kind of practitioner, assisted by whole-time advisers. The Minister could tell the Board how far its proposals were likely to be supported by himself and implemented by the Dail. The author is particularly severe on the lack of antituberculosis measures, to which he would give priority in any scheme for an improved medical service. He points out that the death rate for tuberculosis has declined in most other countries, "whereas Eire has actually allowed the disease to gain on us."

We cordially recommend this essay to the attention of our colleagues in Eire and to the Department whose obvious duty it is to try to remedy the state of things shown in its pages.

A. C.

MENTAL HEALTH AND THE WAR

The War and Mental Health in England. By James M. Mackintosh, M.D. (Pp. 91.) New York: The Commonwealth Fund; London: Oxford University Press. 1944.

This small book, comprising lectures by Prof. James Mackintosh for American audiences, is so full of material that a summary cannot do more than hint at the principal points of practical interest, especially those connected with preparing for the peace which we all hope may not be far distant.

The earlier part of the book is principally of historical interest, and is devoted to a masterly summary of the many problems of adaptation that beset different sections of the community—for example, the new soldier, the industrial worker, the housewife, the child, the aged, the hospital patient, and the student. While emphasizing how magnificently people have stood up to their ordeals, he asks whether many of the painful experiences may not have left their effects which may one day appear on the surface. Certainly we must expect that much chronic illness in the future will be attributed to the war. The separation of children from their parents for long periods, for example, is expected to be a major source of problem later; not only on the return to the home, but in more subtle ways afterwards.

The need to have an organization ready to take care of the manifold problems of resettlement is one that should be recognized officially in a comprehensive way. The Tomlinson report left something to be desired in this respect. It recognizes the existence of neuroses and psychoses, but not of the mental aspect of ailments diagnosed as physical—a much more extensive problem. It contemplated also the readjustment of the patient in industry; but the problem is a human one of much wider scope than that.

It is clear that much education, not only of the public but of official bodies, is still required. It is to the Provisional National Council for Mental Health that Prof. Mackintosh looks to "make the mental health movement in England to learn to stand on its own feet" as an organization supported by the people. He feels that whole-time salaried officials are essential for bringing this about. Voluntary workers alone cannot do it—for want of time, and very often from lack of technique. To meet the greatly increased demand for trained workers there is bound to result from a social security programme Prof. Mackintosh has in view a common two-year training, with a third year for those who wish to specialize in medical-social work, psychiatric social work, industrial welfare, etc.

These are samples of the activities that he sees as part of a systematic education of the community in mental health; but he does not forget that a national ideal of some sort is necessary too. He does not, however, attempt to prescribe what the nature of the national ideal shall be beyond a capacity for enjoying work and making good use of leisure.

REGIONAL ANALGESIA

Regional Analgesia. By H. W. L. Molesworth, F.R.C.S. (Pp. 90; illustrated. 8s. 6d.) London: H. K. Lewis and Co. 1944.

The need for a new book on the subject of regional analgesia might appear doubtful, seeing that there are already several very capable treatises to be obtained, but Mr. Molesworth's has at least the merit of concentrating the main principles into some ninety pages, and, as stated in the preface, it represents personal experiences, which are always of value to the reader. It seems that interest in local, regional, and spinal analgesia is increasing in this country; there can be no doubt that in many circumstances there is much to be gained by the employment of one or other of these methods.

In this book there is nothing novel in the methods described, but the matter is presented in a succinct way which avoids all ambiguity. After a consideration of general principles and of certain details of technique, the various applications of regional analgesia are dealt with, as is appropriate, on a regional basis. It is to be noted that the author's preference is for the well-tried novocain and percaine solutions in suitable strengths. The use of the older term "novocain" in place of the official "procaine" throughout the book is a wise precaution against any tendency to muddle "procaine" and "percaine," especially as the text does not refer to the latter substance under its newer designation "nupercaine."

The final chapter gives a very brief summary of the methods of spinal analgesia in common use. There are numerous illustrations—clear line drawings for the most part—showing the distribution of the nerves and the exact points at which the injections are made. The book will be a useful and handy guide to those who propose to employ regional analgesia more extensively in their practice and who need a short introduction to the subject.

Notes on Books

Modern Treatment Year Book, 1944, is the tenth in the series of collected papers written for the *Medical Press and Circular* under the editorship of Surg. Rear-Adm. CECIL P. G. WAKELEY and republished by Baillière, Tindall and Cox at 16s. As in recent years, the contents are grouped into those on miscellaneous topics and those on war medicine and surgery—twenty-one of each. There is no unifying thread, but almost every article is mainly concerned with treatment, and some of them have bibliographies.

Casualty Work for Advanced First-Aid Students, by A. W. MACQUARRIE, M.B., Ch.B., is published by E. and S. Livingstone at 4s. 6d. Still the making of these books has no end, but the end of the war is in sight. Still road accidents abound, and the facts within the covers of this pocket-book are needful for street and other first-aid work. The volume contains but little new, and some of its old is very antiquated. "Fractures have been," and still are, "classified" as simple, compound, etc., so it is not so "simple" as it appears. Here "open" and "closed" are used for wounds, but not for fractures. It is perhaps questionable to state that "any injury is a wound." Fifty-five pages on transport, out of 223 pages in all, might be thought to be a high proportion in a manual of this type. As a "refresher" book and one readily carried in the pocket, this recent production may even now be of use.

Preparations and Appliances

APPARATUS FOR CONTINUOUS INTRAVENOUS ANAESTHESIA

Major WALLACE M. DENNISON, F.R.C.S.Ed., R.A.M.C., writes:

Continuous drip anaesthesia is becoming increasingly popular and has already proved its value in battle surgery. Many types of apparatus have been described, but essential parts of most of them are not available in Service hospitals. After many experiments the following apparatus was assembled from parts available in all military hospitals. It is at present in use in our hospital, and in the hands of Capt. W. G. Taaffe, R.A.M.C., has proved to be foolproof.

A three-legged douche-stand on wheels forms a secure and mobile base for the apparatus (Fig. 1). To one of the four

FIG. 1

uprights a wooden-panel is clamped. This panel carries the saline and pentothal containers, fine-adjustment screws, and a double-drip bulb. The saline container is the standard 500-c.cm. glucose-saline-giving bottle, held in position by a shoulder

collar and a strong spring clip (Fig. 2). The anaesthetic solution is carried in the barrel of a 20-c.cm. syringe fitted with a rubber stopper perforated to carry a glass tube with filter wool. The double drip is formed from the filter from a Horrocks infusion

FIG. 2

set, the doubly perforated flanged bung from a transfusion set, and two short pieces of glass tubing drawn to a fine point. The anaesthetic container and the drip bulb are held in position by the clips on the clip rack from a 20-c.cm. Record syringe case. Both clip racks are permanently fixed to the base-board. Fine-bore rubber tubing is used throughout, and the needle (Wassermann size) is attached to a glass vein-seeker.

After filling the pentothal container (using either its own plunger or one from another syringe) it can be temporarily laid aside, if desired, by affixing the sealed hub of a hypodermic needle to prevent the contents running out. It is the practice here to add 1 c.cm. of nikethamide (coramine) to 20 c.cm. of pentothal solution. Before inserting the needle both fine-adjustment screws are tested and all air is expelled from the tubing. The arm is splinted in the usual fashion and a sphygmomanometer cuff is employed to render the veins prominent. The saline flows continuously at 40 to 60 drops a minute, and the anaesthetist need only give a light touch with two fingers to turn off the pentothal. The intravenous anaesthesia is combined with light gas-and-oxygen when required. Incidentally, the anaesthetic is never started until the oxygen is in the theatre and turned on.

The holes in the fine-adjustment screws were countersunk and the apparatus rapidly assembled by Pte. Chanter, R.A.M.C., operating-room assistant.

A HISTAMINE-PROTEIN COMPLEX

Messrs. Parke, Davis and Co. have prepared a histamine-protein complex, "Lertigon," which is intended for use in the treatment of allergic conditions. The assumption underlying Lertigon is that allergic manifestations are due to the release of histamine when the reaction between some antigen and its antibody takes place within the cells of the tissues and not in the extracellular spaces or in the blood stream. Lertigon is a histamine-protein complex which, when injected, produces antibodies which not only neutralize the histamine-protein complex, but, it is hoped, also neutralize the histamine, following Landsteiner's work. The protein which is used to unite with histamine is horse serum globulin, treated, presumably with alkali, to remove its antigenic properties. It is thus said to be "despecciated." It is then combined with histamine as an azoprotein combination. Clinical results are said to show that the injected complex produces in patients a precipitin so that the patient's serum neutralizes histamine *in vitro*. In the patients themselves there is said to be a reduction in the threshold for a skin test with histamine; presumably a larger dose is needed to produce the usual capillary dilatation and wheal formation.

Lertigon is recommended for the treatment of allergic forms of bronchial asthma, vasomotor rhinitis, eczema, urticaria, and contact dermatitis, in which either the allergen is not discoverable or complete avoidance of the allergen cannot be obtained. It is given by intradermal injection in doses of 0.01 to 1.02 c.cm.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY SEPTEMBER 30 1944

HYPOGLYCAEMIA

It is still common to regard hypoglycaemia as a dramatic condition due either to a tumour of the islet cells of the pancreas or to some other obscure endocrine condition or to overdosage with insulin. The first cause is certainly, as Lawrence¹ pointed out in a recent letter to this *Journal*, of considerable rarity and the last unlikely to be missed; and it may well be that spontaneous hypoglycaemia has recently been cited too often as the explanation of obscure symptoms. Hypoglycaemia should be diagnosed only when the symptoms are associated with a blood-sugar level low for the individual in question; when they can be reproduced by a reduction of the blood sugar to this level by fasting, exercise, or the injection of insulin; and when they can be relieved by the raising of the blood sugar by means of glucose. Even when these criteria are borne in mind, opinion is gaining ground that many cardiac and neurological symptoms may be due to a blood sugar which, though not necessarily below the limits of the usual, has fallen too rapidly or to a level uncomfortably low for the individual concerned. The level of blood sugar at which symptoms may occur varies from one individual to another. Hill, Sargant, and Heppenstall² have stated that people with cerebral dysrhythmia are particularly susceptible to lowering of the blood sugar and may have symptoms at what are usually regarded as normal levels. They described³ one patient in whom abnormal behaviour developed together with an unstable electro-encephalogram when the blood sugar sank to 100 mg. per 100 c.cm.: in one such incident he murdered his mother. A patient described by Romano and Coon,⁴ whose behaviour was usually correct, suffered from episodes of uninhibited emotional behaviour due to an islet cell tumour and was cured by its removal. Parfitt,⁵ in reviewing the neurological and psychological effects of hypoglycaemia, quotes references to manic, confusional, paranoid, catatonic, and hallucinatory states, hysteria, automatism, amnesia, stupor, depression, and narcolepsy. Happily most of us just feel tired.

Cardiac symptoms in hypoglycaemia have been described by several authors in recent years. In 1931 Waters⁶ described a patient whose paroxysms of tachycardia were associated with a low blood sugar, and two years later Sippe and Bostock⁷ pointed out that angina might be precipitated by hypoglycaemia. In 1935 Harris⁸ described the concurrence of hypoglycaemia with tachycardia, palpitations, extrasystoles, a sense of suffocation, and precordial

pain. Messenger⁹ in 1938 observed various signs of overacting heart in patients receiving insulin shock treatment for mental disorder. Recently Harrison, Finks, and Winston-Salem¹⁰ in America and Raymond Greene¹¹ in this country have independently drawn attention to the similarity in symptoms between some cases of hypoglycaemia and some cases of effort syndrome. Harrison and his colleagues described 31 patients who suffered from symptoms identical with those of effort syndrome two or more hours after meals. Their trouble was reproducible by injections of insulin and relieved by sugar. They confirmed the important observation of previous workers that the usual glucose-tolerance test is almost valueless in diagnosis. Only 3 of their 31 patients had low fasting blood-sugar levels, and two of them had lag storage curves. The test had to be carried on for 2 to 4 hours to disclose the low sugar value in many patients. Even so the values were sometimes low only for the individual patient and not in comparison with the normal. Some patients have symptoms of hypoglycaemia at a level of 70 mg. per 100 c.cm., whereas others fail to have symptoms at much lower values. The body appears to accustom itself to such low levels, and patients with Simmonds's disease, Addison's disease, anorexia nervosa, and idiopathic steatorrhoea often remain comfortable at levels at which diabetics would go into hypoglycaemic coma. Of the 31 patients described by Harrison and his colleagues, 14 had previously been said to be suffering from "cardiac neurosis." Of Greene's 5 patients all had been labelled "effort syndrome." That the label may fit is suggested by the fact that 7 of Harrison's 14 and 2 of Greene's 5 continued to be neurotic individuals after their cardiac symptoms had been relieved. Greene points out that the similarity of symptoms is only to be expected. The symptoms of effort syndrome are the somatic accompaniments of fear, and are due to excessive secretion by the adrenal medulla. In hypoglycaemia the early symptoms are due to the same cause, evoked not by fear but by a natural physiological reaction designed to increase the mobilization of liver glycogen. The hypoglycaemia of these patients may itself be due to psychological conditions, but whether or not this is so it can be relieved by dietetic treatment.

This treatment for many years consisted of a high intake of carbohydrate, and it is true that symptoms of hypoglycaemia may be relieved by eating sugar. In 1943 Thorn, Quinby, and Clinton¹² published a comparison of the metabolic effects of isocaloric meals of varying composition. The results supported Conn's¹³ opinion, which had long been gaining ground, that better results would be obtained by a high-protein diet. A high-carbohydrate breakfast of 400 calories (containing only small quantities of fat and protein) results in an immediate rise in the blood sugar, followed an hour or so later by a fall, which, two to three hours after breakfast, reaches a level well below the fasting value. There is then a gradual climb to fasting levels which are not reached till some five hours after breakfast. A high-fat breakfast (containing only small quantities of

¹ *British Medical Journal*, 1943, 2, 760.² *Ibid.*, 1944, 1, 162.³ *Lancet*, 1943, 1, 526.⁴ *Psychosomat. Med.*, 1942, 8, 283.⁵ *Proc. roy. Soc. Med.*, 1937, 31, 137.⁶ *Scutliff med. J.*, 1931, 24, 249.⁷ *Med. J. Austral.*, 1933, 1, 207.⁸ *Southern med. J.*, 1935, 28, 959.⁹ *Ann. intern. Med.*, 1938, 12, 853.¹⁰ *Amer. Heart J.*, 1943, 26, 147.¹¹ *Lancet*, 1944, 2, 307.¹² *Ann. intern. Med.*, 1943, 18, 913.¹³ *J. Amer. med. Ass.*, 1940, 115, 1669.

carbohydrate and protein) likewise produces an immediate rise in the blood sugar, followed by a more gradual fall to a trough at five hours, just when the carbohydrate has risen again to fasting levels. On the other hand, a high-protein breakfast (containing only small quantities of carbohydrates and fat) gradually raises the blood sugar, which reaches its maximum after only two hours and thereafter remains almost level for another three. The value of a "good mixed diet" is beautifully shown. The blood sugar at first rises rapidly by reason of the carbohydrate and fat. The level is maintained by the protein. As the old wives say, "Bread-and-butter doesn't stay by you, it's the cut off the joint which does that, not the two veg." Those of us who find ourselves unduly tired at remembrance of the last meal grows dim may comfort ourselves. We haven't got tumours of the pancreas, and we shall be all right again when we can throw that roll at the waiter's head and order a *tournedos Rossini*.

INFANTILE GASTRO-ENTERITIS

"Infective enteritis or diarrhoea" among children under 2 years of age, with a death roll of 2,000 to 3,000 every year, ranks second to pneumonia as a killing infection in infancy. The majority of deaths occur in the first year of life, and are to be attributed mostly to the diarrhoea and vomiting of dubious and possibly diverse aetiology which masquerades under a variety of names from summer diarrhoea to *cholera infantum*. In this country dysentery and salmonella infections are rare, and rarely fatal, in the first year of life. The incidence of non-specific enteritis, on the other hand, is difficult to gauge because it is not generally notifiable, but the extent of the problem may be guessed from data from LCC hospitals in pre-war years. Thus in 1936 1,692 children (under 2) with enteritis were treated in these hospitals and 535 died; in 1937 the corresponding figures were 1,759 cases with 438 deaths.¹ It has long been recognized that gastro enteritis is predominantly a disease of artificially fed infants living in urban poor-class districts, and Gardner² has lately made an interesting analysis of its ravages in town and country communities. Thus for the years 1935-8 the diarrhoeal mortality rate was 5.6 and the infant mortality 56.4 for England and Wales, 2.4 and 49.6 for rural districts, 5.9 and 63.3 for county boroughs, and 12.1 and 60.3 for metropolitan London. This high diarrhoeal mortality in the London area did not affect infants in the first month of life as it did in the industrial North, but in the succeeding months of the first year infective enteritis was the chief cause of deaths among infants in Greater London. Comparisons with other cities showed that for the same period (1935-8) Birmingham had a diarrhoeal mortality of 6.9, Manchester 5.8, and only Newcastle, with an excessive infant mortality of 83, had a higher diarrhoeal death rate (13.8) than metropolitan London. Statistical analysis also showed that, until 1929, London shared in the general downward trend of diarrhoeal mortality, whereas in the ten years since then the rate for London has been rising, while those for the county boroughs

have continued to fall. An explanation of this disturbing feature is hard to find. Differences in ascertainment and certification may be partly responsible, but an important contributory factor may be a greater tendency in the London area to send young children into hospital (The figures relate to pre-war years, so that wartime nurseries are not involved). It is now generally agreed that children under 1 year of age should not be admitted to hospital for minor ailments unless they can be nursed in isolation, yet many infants with mild dyspepsias are notified as cases of infective enteritis and cannot be refused admission to municipal hospitals. Owing to shortage of isolation accommodation a fair proportion of these infants have to be nursed in open wards by the barrier or bed-isolation technique, which is not effective enough to prevent re-infection and relapses. Thus in the careful study reported by Drs Alexander and Eiser in our present issue the relapse rate was 31% among 67 infants nursed in the barrier ward and only 8% among 73 babies nursed in cell wards. When it is added that 6 of the 8 deaths in their series followed a relapse, the importance of proper isolation for babies admitted to hospital becomes obvious. With the isolation technique evolved by Gladys Dick for the Cradle at Evans-town no instance of cross-infection with enteritis occurred among 1,650 homeless babies nursed for an aggregate of 66,000 days.³ By contrast the diarrhoeal death rate among London's illegitimate infants is so high that such an infant has a 1 in 40 chance of dying of this disease before reaching its first birthday.

Apart from isolation, the care and treatment which the infant with diarrhoea and vomiting receives may play a major part in the outcome. Case mortalities in hospital have varied from 30 to 60%, and where a division is made into the severe dehydrated cases and mild infections the fatality rate in the former group has rarely been less than 50%.⁴ A case mortality of 11.6% among 69 dehydrated infants in Drs Alexander and Eiser's series of 140 cases is therefore an achievement which must attract attention. Their plan of campaign was to search for and treat any forms of parenteral infection, to correct fluid loss by intravenous Hartmann's solution supplemented by half-strength serum or plasma, to return as quickly as possible to a diet sufficient to satisfy the patient's requirements, and to combat shock in collapsed and dehydrated infants. Secondary anaemia, a common feature, was corrected by iron and whole blood transfusions. This regime may not seem very different from the treatment advocated by other workers, except perhaps in the early and more frequent use of plasma or serum. Probably what matters most is the intelligence, skill, and enthusiasm with which treatment is applied, and the results obtained in this series reflect credit on both the medical and nursing staffs who carried it out.

Drs Alexander and Eiser stress the aetiological role of parenteral, particularly upper respiratory, infection in gastro enteritis, and obviously it may be an important factor both causally and as a secondary focus which aggravates the condition. However, many infants with diarrhoea and vomiting have no parenteral infection, and other infants with respiratory disease do not develop diarrhoea.

and vomiting. A causal virus, gaining entry by the oropharynx like the virus of poliomyelitis and spread from both the respiratory and alimentary tracts, could be postulated to explain these anomalies. Meanwhile controlled tests might be made of the newer sulphonamides (e.g., succinyl sulphathiazole) for the treatment of intestinal symptoms. Liver damage is often an outstanding feature in fatal cases, suggesting either absorption of toxic substances from the gut or a deficiency in some essential amino acid. This aspect of the problem deserves study, and the use of protein hydrolysates either orally or intravenously seems worth a trial in gastro-enteritis. But in this as in other infections prevention is better than cure, and there is urgent need for a publicity campaign to persuade both doctors and the public that breast-feeding for 6 months is the best antidote for this serious drain on infant life.⁵

CHOLINESTERASE AND MYASTHENIA GRAVIS

The search for an explanation of the mechanism responsible for the causation of myasthenia gravis has been greatly stimulated in recent years by the development of knowledge of neuro-muscular transmission processes. Theoretically, myasthenia gravis might be due to inadequate release of transmitter substance at the neuro-muscular junction; to an unduly high threshold of excitability of the motor end-plate to the chemical transmitter; or to an excessively rapid destruction of the transmitter substance. Acetylcholine appears to be the chemical transmitter at the neuro-muscular junction. The existence of an enzyme capable of hydrolysing acetylcholine and acetic acid was established by Loewi and Navratil⁶ in 1926. Recently Mendel and Rudney⁷ have shown that the "cholinesterase" present in blood serum and certain tissues is a non-specific enzyme capable of hydrolysing not only choline esters but non-choline esters as well. Apart from this "pseudo-cholinesterase" a specific cholinesterase hydrolysing exclusively choline esters was demonstrated in brain tissue and the red blood corpuscles of some species. Mendel and Rudney concluded that measurements of cholinesterase activity in which acetylcholine is used as substrate give an inaccurate picture of "true" and "pseudo" cholinesterase in any mixture of the two enzymes. It is probable that some controversy in the literature with regard to cholinesterase levels in serum in certain pathological conditions might be resolved if this recent distinction between specific and non-specific acetylcholine-splitting enzymes were taken into consideration.

Various observers tried to find evidence for the conception of a faulty neuro-muscular chemical transmission in cases of myasthenia gravis in terms of a pathologically high cholinesterase concentration in the blood. However, this was not found to be the case, for low serum enzyme levels are claimed by Stedman and Russell,⁸ and no significant differences from normal were found by Jones and Stadie⁹; most recently Wilson and Stoner¹⁰ found the serum cholinesterase activity within normal range in 12 out of 14 patients suffering from myasthenia gravis, and 2 subjects showed low enzyme levels. With regard to the myasthenia gravis problem, serum enzyme estimations might not necessarily give a relevant picture of the situation, and it is

perhaps somewhat surprising that, so far, only two reports have been published of enzyme determinations in myasthenic muscle itself (Jones and Stadie⁹; Goodman, Carlson, and Gilman.¹¹) There was no evidence of any material increase in cholinesterase activity of myasthenic as compared with normal muscle, and at present there is no experimental support for the initial working hypothesis that the muscular weakness in myasthenic patients is due to an excessively rapid destruction of the chemical transmitter, acetylcholine, by high concentrations of cholinesterase at the neuro-muscular junction or in the blood. And myasthenic patients are not known to suffer from any derangement of autonomic functions which depend on cholinergic transmission of nerve impulses. On the whole, evidence suggests that the basic disturbance of the myasthenic is an elevation of the motor-end-plate threshold to the effects of motor-nerve impulses (Gammon, Harvey, and Masland¹²); this conception is supported by the recent work of Wilson and Stoner,¹⁰ who demonstrated in the serum of myasthenic patients not under prostigmin treatment a substance, partially soluble in alcohol, which interfered with neuro-muscular transmission and produced a curare-like paralysis on the isolated nerve-muscle preparation of the frog.

The results of cholinesterase determination during exercise and during circulatory stasis are difficult to interpret. Stoner and Wilson¹³ found no change in the serum enzyme activity during exercise under ischaemic conditions in normal and myasthenic subjects (without and with prostigmin treatment). However, Croft and Richter¹⁴ observed a shift of the enzyme from the red cells into the serum during muscular exercise. The significance of these findings is not clear. Recent work has shown that definite changes in cholinesterase activity can be produced by certain hypnotics. Prolonged administration of phenobarbitone soluble or phenyl-methyl barbituric acid reduces the amount of cholinesterase in serum by approximately 22% of the average amount of enzyme present in untreated subjects (Schütz¹⁵); the serum enzyme concentration remained unaffected by administration of a single large dose of these drugs. These findings were confirmed in guinea-pigs (Schütz¹⁶), where, in addition, a diminution of the enzyme content was observed in skeletal muscle and in the spinal cord. It is possible that the low enzyme levels reported in epileptics by Stedman and Russell⁸ and Tod and Jones¹⁷ are due to the chronic use of barbiturates in this condition.

OPHTHALMOLOGY IN THE FIELD

The ophthalmic surgeon in the Forces has an exacting task. A civilian ophthalmologist is more a physician than a surgeon, and more of a judge than a physician. It may be no mere coincidence, therefore, that Major H. B. Stallard in two illuminating articles¹⁸ on ophthalmic war surgery can record that in four years of service he acted on occasion as a general surgeon and as P.T. and games officer for sixteen months to the exclusion of any clinical work except for frequent "free from infestation" inspections of several hundred troops. That he should command a rifle company in defence of a hospital against possible attacks from parachutists, fifth columnists, and such-like is almost an anticlimax. And on top of this there is a record of solid ophthalmic work carried out under trying condi-

tions. A daily routine which begins, in military terminology, at 06.15 and ends at 22.30, and treatment of casualties produced by battle, accident, and stupidity caused by those "fools who despite warning orders allow their curiosity full reign in the inept dismantling of hand grenades, fuses, and mines, or in boisterous play throw hand grenades near each other," gave ample opportunity for a variety of experience. Stallard's articles show that experience under difficult conditions can add substantially to our knowledge. New plastic operations for the reconstruction of colobomata and much loss in the eyelids have been developed, and, what is of particular interest, a technique for the extraction of intraocular foreign bodies by the posterior route. Intraocular foreign bodies seen in the present war are generally feebly magnetic, and their removal is a technical problem of first magnitude. The general aspects of this problem were defined by Mr. L. H. Savin last year in a Hunterian Lecture at the Royal College of Surgeons, when he showed from human and experimental material that aluminium alloys, as these foreign bodies generally are, are far from innocuous to the eye, while their removal involves great difficulties in accurate location and new techniques. The work recorded by Stallard shows that the problem may not be so insuperable as is generally believed. The two outstanding ophthalmic difficulties the present war has brought out are the non-magnetic intraocular foreign body and the multiple injuries, including bilateral eye injuries, produced by land mines. The advent of the sulphonamides and of penicillin have, however, contributed largely to successful treatment. The perusal of the statistical data supplied by Stallard is far from depressing.

PAREGORIC

We remember that the only cough mixtures which were appreciated by the mothers in the out-patient department were those which contained paregoric, or tinct. camph. co. as it used to be called. It was paregoric which stopped the children from coughing all night. We did not doubt that its virtue lay in the tinct. opii it contained, and that rationalization would one day sweep it away. It is therefore interesting to discover that a pharmacologist has thought it worth while to measure its expectorant action and to compare it with that of its several constituents, and has been rewarded by finding that the expectorant effect of paregoric is greater than the sum of the effects of the constituents, and, above all, that like good wine it improves with age. It is the old paregoric, brown with some years of storage, which is the best. Eldon Boyd and Marion MacLachlan,¹ working at Kingston, Ontario, have delved into the history of paregoric. They conclude that it was the final form of many mixtures containing opium which go back as far as the Greeks, Romans, and Arabians. They are not prepared to regard paregoric as invented by Le Mort, who was professor of chemistry in Leyden from 1702 to 1718. He concocted a mixture containing honey, liquorice, flowers of Benjamin, opium, camphor, oil of aniseed, salt of tartar, and spirit of wine; this mixture became official under the name of Elixir Asthmaticum in the *London Pharmacopoeia* of 1721 and is commonly regarded as the original paregoric. But beside their historical research (which is only touched on here) Boyd and MacLachlan have used a method of measuring expectorant activity devised by Perry and Boyd² in 1941. They insert a tracheal cannula into the lightly anaesthetized animal and allow it to breathe warm moist air. Since the animal is tilted tail-upwards, the outflowing secretion from the

respiratory passages can be collected and measured. Cats, rabbits, rats, guinea-pigs, and even hens can all be used, and the administration of paregoric by mouth causes an increased output of secretion, which is most striking in the rat—three- to four-fold—and is due to a reflex from the stomach, as it does not occur when the gastric nerves (branches of the vagus) are cut. Boyd and MacLachlan have found that tinct. opii, camphor, and alcohol all play a part in this expectorant effect, alcohol being particularly potent. Benzoic acid and oil of anise, on the other hand, have no effect. The authors have some evidence that paregoric itself has a more prolonged expectorant action than the sum of its component parts, which if true argues extremely keen powers of observation in those who first compounded it. Finally, they state that old paregoric is much better than fresh; they regard their experiments as clearly demonstrating this, and suggest paregoric should stand for at least two or three years.

CHEESE-BORNE OUTBREAK OF TYPHOID FEVER

In the *Journal* of June 12, 1943, we referred to an outbreak of typhoid fever in Manitoba traced to the consumption of immature cheddar cheese made from infected milk. Another outbreak, attributed to the same cause, has been described in Canada by Gauthier and Foley.¹ The cases occurred during September and the first week of October, 1941, among a group of adjacent villages in Champlain County, Quebec. Altogether 40 cases were notified, of which 6 proved fatal. Over 60% of the patients were in the age group 10–29 years, and the number of male patients was nearly double that of females. Such an age and sex distribution was suggestive more of an article of food as the vehicle of infection than of water or milk. Careful inquiry narrowed the source of infection down to a butter and cheese factory (R) in the neighbourhood. Since only 24 of the patients had eaten butter from this factory, suspicion became centred on the cheese. This was confirmed, partly by finding that every patient had partaken of the cheese, and partly by the occurrence of four cases (included in the 40) in a doctor's family in Montreal, to which cheese from the R factory had been brought back by the doctor himself after a visit to Champlain County. How did the cheese become infected? Investigation at the factory disclosed no history of typhoid fever among any of the employees, and repeated samples of faeces proved bacteriologically negative. The cheese itself had been made from raw milk and offered for sale within ten days of manufacture. The milk came from eighty farms, but on none of these did inquiry reveal the previous occurrence of typhoid fever, with the exception of one farm on which there was a known carrier, Mrs. C. A., who had received instructions about the limitations of her work. On another farm a child had had a mild fever in August, 1941, lasting for 2 to 3 days, and examination of his blood serum disclosed titres of 1/50, 1/75, and 1/25 for *Bact. typhosum* O, H, and Vi antigens respectively. He had never been inoculated against enteric fever, so that this result was highly suggestive of the carrier state. Eight specimens of his faeces, however, proved negative, and, rightly or wrongly, this boy was discounted as a probable source of infection. On the other hand, Mrs. C. A., the known typhoid carrier, admitted that she had disobeyed orders and had milked cows during the latter part of August. The milk had been sold to the R cheese factory. Cultures of the typhoid bacilli were isolated from each of the 40 patients.

¹ *Canad. med. Ass. J.*, 1944, 50, 338.

² *J. Pharmacol. exp. Therap.*, 1941, 73, 65.

¹ *Canad. publ. Hlth. J.*, 1943, 34, 543.

None of the cultures could be typed locally by the bacteriophage method, but 30 of them were sent, together with the strain from Mrs. C. A., to Dr. Craigie, who found them all to be imperfect Vi forms belonging to Group D1. The conclusion was therefore drawn that the cheese had been made from raw milk infected with typhoid bacilli derived from the typhoid carrier, Mrs. C. A. Since the cheese had been offered for sale ten days after its manufacture, typhoid bacilli had not died out completely.

This story illustrates once again the danger of eating immature cheese. Before the war British practice was to allow cheddar cheese to ripen for 5 to 9 months at a temperature of about 50 to 60° F. There is reason to believe that this time was sufficient to allow all pathogenic organisms, including tubercle bacilli, to perish. During the war, however, the period of ripening has been shortened. In addition, a considerable quantity of cheese is imported from the United States which has never been properly ripened at all; instead it has been stored in a refrigerator, brought over here, and sold often within a few weeks of its arrival. It is very doubtful whether such cheese can be regarded as safe for human consumption. Indeed, recent observations by Campbell and Gibbard² show that cheddar cheese made from milk artificially infected with typhoid bacilli and stored at 40 to 42° F. may still be infected after ten months. From the public health point of view it would be advisable to insist that cheese made from raw milk should be ripened for at least three months at 50 to 60° F., and for at least 9 months at 40° F. Otherwise the milk should be pasteurized before being run into the cheese vat.

COLITIS AND X RAYS

In view of the sensitivity of the intestinal mucosa to penetrating radiation it is perhaps surprising that ulcerative colitis as a sequel to irradiation of the abdomen should have escaped recognition for so long. For in the last four years Engelbreth-Holm³ has found, among 100 necropsies of carcinoma of the cervix in the Copenhagen Radium Centre, four in which death was due to ulcerative colitis developing after x-ray treatment. The lesions macroscopically and microscopically were identical with those seen in idiopathic ulcerative colitis, and since they involved the entire colon they could not be ascribed to overdosage or direct radiation injury; indeed, one case was given only palliative x-ray treatment with the relatively small tumour dose of 2,200 r in 36 days, and the other three had combined radium-x-ray therapy on standard lines. Diarrhoea and proctitis are often encountered towards the end of the radiotherapy course, but they are readily controlled by opium and usually subside within a week of stopping the irradiation. In the four cases reported here, however, the diarrhoea became purulent, the disease took a rapid course, and all four patients died after 9 to 30 days of illness. There was no "radiation ulcer" in the rectum, and no evidence of endarteritis in the microscopical picture⁴; and in any case the typical map-like ulcerations were as well marked in the transverse colon far away from the field irradiated as in the sigmoid loop. Engelbreth-Holm cites Chrom's observation that the intestinal mucosa, normally impermeable to the bacteria within the bowel, loses its efficiency as a barrier after x-irradiation, and suggests that the occurrence of extensive ulceration in only a few of the numerous patients submitted to a uniform treatment may be due to the presence of pyogenic bacteria

in those cases. To explain the ulceration in parts of the colon not directly irradiated he turns to the work of Lium and Porter⁵: they demonstrated that mucus normally protects the mucous membrane from ulceration, that spasm of the musculature emptied the goblet cells, and that ulceration then resulted from the slightest trauma or even from continued muscular spasm alone; hence the maximum distribution of the ulcers in the rectum, where the musculature is strongest, and next along the taeniae coli. Holm's observations thus afford support for Lium's view that muscular spasm plays a decisive part in the aetiology of idiopathic ulcerative colitis, for rectal tenesmus is often present in radiation proctitis; irradiation of the explants of colon in Lium's experiments should afford further information of value. It seems probable that ulcerative colitis has been overlooked as a cause of morbidity and mortality after radiotherapy of abdominal and pelvic neoplasms, and that when diarrhoea and rectal tenesmus fail to respond to opium, to starch or olive-oil enemata, or to mineral oil by mouth, the "dry powder" treatment for which Soper⁶ claims success might protect the denuded mucosa and enable healing to proceed.

HEALTH OF AMERICAN TROOPS IN THE PACIFIC

A little-publicized aspect of the work of the medical authorities of the United States War Department is the constant attention given to the health and sanitary conditions in the islands of the Pacific. Before the recent landing in Guam, for example, a complete survey had been undertaken by the Army Medical Department, and information on the water supply, sewage disposal, and especially on diseases common to the area, was available to every medical officer taking part. Health measures were, of course, in operation under the U.S. Navy before the Japanese captured the island in 1941, and there had been a great improvement in conditions generally during the Navy's forty years' administration. But the health of an army is constantly threatened in the climate and circumstances prevailing in the Pacific Islands, and in Guam the natives have been slow to adopt sanitary measures. The survey issues the obvious warning that all water, regardless of its sources, must be regarded as unsafe until proved otherwise; but of more interest, as reflecting continued occupation of the island, is the instruction to M.O.s to take steps as soon as they land to control flies, which are responsible for the spread of "enteric disease, yaws, and diseases of the skin." Twenty-five per cent. of Guam natives have hookworm, and it is therefore recommended that camps should be some distance from places frequented by natives and that no native should be allowed to enter a camp area. Men are advised also to wear shoes about the camp to guard against hookworm infection, and, to lessen the risks of their contracting dysentery and diarrhoea, are forbidden to eat in native houses. The U.S. Office of War Information states that similar surveys have been prepared for other enemy regions where American troops are likely to go.

The Royal College of Physicians announces that Sir Edmund Spriggs will deliver the Harveian Oration on Wednesday, Oct. 18, in the clinical lecture theatre of the Royal Infirmary, Manchester, at 3.45 p.m. Subject: "The Harveian Method in Literature."

EVARSAN

Neoarsphenamine (Evans)

Progressive research at The Evans Biological Institute has yielded a highly purified neoarsphenamine of exceptional quality.

Batch Uniformity

Evarsan shows uniformity in chemical and biological properties from batch to batch.

Low Toxicity

Animal tests show that the toxicity is at least nineteen per cent. lower than the official minimum requirements for neoarsphenamine.

Manufactured and tested under U.K.
Manufacturing Licence No 18.

High Therapeutic Activity

Despite low toxicity, therapeutic activity is maintained at a high level and for most batches is about fifteen per cent. higher than the official minimum requirements.

Stability

Evarsan exhibits a high degree of stability.

Approved by the Ministry of Health for use in Venereal Disease Clinics.

Full details of the use of Evarsan and other Evans products in the treatment of syphilis are contained in a handy pocket-book "The Treatment of Syphilis" free on request to :

THE MIDDAY SCHOOL MEAL

A STUDY OF ITS RELATION TO THE SCHOOL WEEKLY
DIETARY OF A GROUP OF SCHOOLBOYS

BY

R. P. COOK, M.B., D.Sc.

W. A. DAVIDSON, M.D., D.P.H.

D. M. KEAY, M.B., D.P.H.

AND

D. G. McINTOSH, M.B., D.P.H.

(From the Physiology Department, University College, Dundee, and the Public Health Department, Corporation of Dundee)

We are investigating the clinical and nutritional status of a group of boys at a trades school in Dundee. This school undertakes the training of pupils for the six building trades. The boys are drawn substantially from the artisan class, and accordingly represent a uniform cross-section of a portion of the working-class community. The average family income is £4 10s. weekly.

This paper, which forms part of a more extended study, is presented to show the contribution of the midday school meal to the total dietary. A short account of some of our findings was given to the Biochemical Society (Cook, Davidson, Keay, and McIntosh, 1944). The relevant data are as follows: (i) Number of subjects, 39 (out of 100 invited to participate); (ii) ages, 14-15 years; (iii) period of study, January to March, 1944. The interest and co-operation of the boys were very striking. The midday meal, which is provided on each of the five school-days (Monday to Friday), is prepared in a central kitchen and distributed to the trades and other corporation schools. A typical meal consists of soup, meat, or fish, with potatoes and greens, and a sweet, usually a milk pudding. Second helpings are allowed. One-third of a pint of milk is given to each boy daily with his midday meal.

Methods of Investigation

Dietary Intake.—Each boy was provided with a tabular sheet, on which he entered his food intake at each meal for one week. One of us personally instructed each pupil, who at the same time received an explanatory leaflet, to serve as an aid in the method of completing the form. The individual foodstuffs were divided into at least 20 categories, and the values of the constituents in each for one week were obtained by the use of: (a) the food-value calculator of Vitamins Ltd.; (b) food tables given by Davidson and Anderson (1940); (c) bread and potato analyses kindly supplied by the Ministry of Food through the courtesy of Sir Jack Drummond, F.R.S., and Dr. Magnus Pyke. The values obtained are for foodstuffs prepared for consumption. While the methods used are admittedly liable to inaccuracies, it is felt that, taking the results as a whole, reliable data have been obtained. That the dietary results are of the correct order is indicated by the fact that determinations of the total nitrogen in 24-hour samples of urine from the boys gave values of protein equivalent ($N \times 6.25$) of 36 to 111 g. per day, mean 68.2 ± 15.4 (cf dietary protein intake, mean 76.6 ± 16.4 , in the accompanying Table). The levels of vitamin A and of ascorbic acid in the plasma also bear a general relationship to the dietary intakes.

Presentation of Results.—These are shown in the Table. The range, mean, and standard deviation are given for each set of values. In calculating the standard deviation we have employed the method advocated by Bradford Hill (1942), and for valuable help in this connexion we are greatly indebted to Mr. Ames L. Imrie, C.A., Depute City Chamberlain, Dundee.

Discussion and Summary

The Table has been made, so far as possible, self-explanatory. The following observations may be of interest:

(i) Considerable individual variations are a striking feature of the total dietary intakes, due probably to the factor of appetite.

(ii) The mean values per day may be compared with the following standards for boys of the same age group, adopted by: (a) the U.S.A. National Research Council (Orr, 1942); (b) the League of Nations Commission (Magee, 1943). Calories (a) 3,200; (b) 2,900;

protein (a) 85 g., (b) 95 g.; vitamin A (a) 5,000 i.u., (b) 3,000 i.u.; vitamin B₁ (a) 533 i.u., (b) 435 i.u.; ascorbic acid (a) 90 mg., (b) 30 mg.; calcium (a) 1.4 g., (b) 1.5 g.; available iron (a) 15 mg., (b) 16 mg. The intakes of ascorbic acid and of calcium fall considerably short of both standards, while the intake of vitamin A is well below the suggested American level.

(iii) The high consumption of national-flour bread is responsible largely for the optimum intake of vitamin B₁, and to a less extent for the satisfactory level of protein recorded. Although not shown in the table, an interesting feature was that a large proportion of the admittedly low ascorbic acid intake was derived from potatoes, particularly "chips."

(iv) The school meal furnishes a valuable contribution to the total dietary of first-class protein, vitamin A, ascorbic acid, and calcium, the percentages being 44.4 ± 10.3 , 67.8 ± 12.2 , 57.8 ± 12.6 , 42.3 ± 10.9 respectively. Values for a comparable group of pupils fed exclusively at home are not available, but from our knowledge of local food habits we feel that corresponding figures for a home midday meal would be most unlikely to equal, and would certainly not exceed, the figures given for the school meal.

Table showing Intake of Dietary Constituents for a Group of 39 Boys aged 14-15

		Total Amount Weekly	Total Amount provided by School Meals (i.e., 5 per week)	Per cent. from School Meals	Amount per Day
Calories	R	9,190-28,186	3,163-8,575	20.0-58.5	
	M	15 341 \pm 3,375	5,347 \pm 1,017	35 68 \pm 7.0	2,191 6 \pm 482 14
Total protein (g.)	R	375-1 032	126-301	23.4-46.0	
	M	546 \pm 114 90	189 \pm 37 24	35 92 \pm 6.1	76 57 \pm 16 41
First-class protein (g.)	R	151-331	65-145	25.7-67.3	
	M	234 2 \pm 45 37	100 8 \pm 17.52	44 4 \pm 10.3	33 46 \pm 6 48
Vitamin A (i.u.)	R	10,300-37,800	7,120-20,460	38.2-84.7	
	M	20,387 \pm 5,334	13,430 \pm 2,655	67 8 \pm 12.2	2,912 4 \pm 762 0
Vitamin B ₁ (i.u.)	R	2,946-7,275	865-2,236	19.2-52.8	
	M	4,119 \pm 841	1,493 \pm 237	37 13 \pm 7.1	588 4 \pm 120-14
*Ascorbic acid (mg.)	R	98-199	51-107	32.3-81.6	
	M	133 7 \pm 26.5	75 3 \pm 14.1	57 8 \pm 12.6	19 1 \pm 3 79
Calcium (mg.)	R	3,770-10,050	1,340-3,850	25.3-61.0	
	M	5,779 \pm 1,448	2,357 \pm 507	42 3 \pm 10.9	825 6 \pm 192 57
Available iron (mg.)	R	47-166	18-48	19.4-53.2	
	M	84 \pm 20.3	30 4 \pm 5.3	37.17 \pm 7.5	12 06 \pm 2 90
Nat. bread (oz.)	R	32-112	—	—	
	M	74 8	—	—	10 7

R = Range M = Mean \pm standard deviation

* The results obtained from three boys during a distribution of oranges, giving values of 69, 58, and 67 mg. per day respectively, are omitted.

(v) The general health of the boys was good. The only lesions possibly attributable to dietary deficiencies were gingivitis (29%) and folliculosis (29%). The relationship of these conditions to the dietary findings is at present the subject of a therapeutic investigation, the results of which we hope to publish later.

Our thanks are due to Dr. W. L. Burgess, C.B.E., and Prof. R. C. Garry for their interest in this work. We are greatly indebted to Mr. Harry Reoch, Headmaster, Trades School, for his keen co-operation.

THE ORDER OF ST. JOHN

The report for 1943 of the Chapter-General, the Grand Priory in the British Realm of the Venerable Order of the Hospital of St. John of Jerusalem, records its gratitude to members of the medical profession who, despite wartime difficulties, continue to instruct and examine classes in first aid. The strength of the St. John Ambulance Brigade at home increased by 11,098 during the year. More than 24,000 members are serving with H.M. Forces, and more than 60,000 with Civil Defence Services. First aid was given to 489,709 persons during the year; and 285,393 patients, including the victims of 9,254 road accidents, were transported in the Brigade's motor ambulances—more than double the 1942 figure.

The St. John Ambulance Brigade over-seas shows a net increase of 204 new Divisions and of 94 Cadet Divisions. In the South Pacific the Queen of Tonga has become an Associate Dame of the Order in recognition of her great services to humanity.

Ophthalmic Hospital, Jerusalem

The report for 1943 of the Ophthalmic Hospital at Jerusalem of the Order of St. John tells of difficulties in administration on account of economic conditions in Palestine. Owing to increased cost of living salaries and wages are constantly rising, and both nurses and domestics are almost unprocurable. As an example of local conditions nurses have left the Bethlehem Mental Hospital to look after their homes, while their parents look after pigs. A sow fetches an enormous price, and some fellahs who were penniless before the war are now reported to be making several thousands a year. Eggs have cost as much as a shilling each, chickens £1, and butter 10s. a pound. New out-patients show a slight decrease through difficulties of travel, and exceptionally cool weather diminished the number of sufferers from epidemic conjunctivitis. Fewer than usual of these cases were complicated by corneal ulceration. Forty of them were treated by instillations of penicillin, but it proved ineffective. Over 90% of out-patients had trachoma.

SCHEMES FOR MEDICAL AND SOCIAL RESEARCH

The Nuffield Provincial Hospitals Trust (16, King Edward Street, Oxford) has issued a memorandum concerning three schemes of social and medical research which are to be assisted financially by the Trust.

Social Adaptation of Children brought up in Institutions

The Provisional National Council for Mental Health is to receive a substantial grant to enable it to undertake this research, which is to be organized and directed by Dr. F. H. Bodman. The war has brought out very strongly the necessity for making provision in this country for homeless, abandoned, and handicapped children. In view of the acute demand, it seems of the utmost importance to ascertain how far and in what respects the institution child is handicapped in comparison with the child brought up in a normal home. There is a general impression among social workers, labour managements, and psychiatrists, who have to deal with children and young persons, that the child brought up in an institution compares unfavourably with the child who has had the benefit of normal home surroundings. But in this country this is so far an impression only and is not based on scientific inquiry; it is felt, therefore, that it would be extremely valuable to make a definite study of the social adaptation of a group of children and young persons who have been brought up in institutions.

Cancer Research in Sheffield

The Sheffield Municipal and Voluntary Hospital Joint Advisory Committee is the joint body "recognized" by the Trust in connexion with the making of grants for development of hospital and ancillary medical services in the area. On the recommendation of the Joint Committee, the Trust is making a grant which will enable the department of pathology to carry out research on the biological effects of ionizing radiation in association with a group of workers on the staff of the Sheffield Radium Centre. The preliminary work contemplated is to investigate the effect of measured therapeutic doses on the hormonal output of the endocrine glands. This is an attempt to prove or disprove the theory that small doses of radiation have a stimulating action on cell growth and function. The work is under the direction of Prof. H. N. Green, M.D., of the department of pathology and Mr. G. W. Blomfield, F.R.C.S., medical director of the radium centre. The preliminary work contemplated should have practical importance in revealing more about the origin and growth of cancer, and is likely to extend over a period of about one year in the first instance. At the end of the year the department of pathology will advise whether the research should be continued.

Infant Dietetics: Research in Scotland

In response to an application from the department of child life and health at the University of Edinburgh, and on the recommendation of its Scottish Advisory Committee, the Trust has undertaken to make, over a period of three years, grants towards further research in neonatal and infant problems, to be carried out at the Simpson Maternity Pavilion, Edinburgh. The research [as announced briefly on Sept. 16, p. 390] will be directed by Prof. Charles M'Neil. The grant will cover the salary of a nurse, appointed by the department, to deal with the nutritional and dietetic problems of child life and health, and when trained she will become a teacher of medical students, pupil midwives, and pupil health visitors. The University of Edinburgh and the Royal Infirmary are to co-operate in this experiment, which, it is anticipated, will afford scope for more practical research within the university department in the subject of paediatrics, by providing an opportunity for closer study of the many physiological problems connected therewith, including the question of prematurity, which plays such a big part in the death rate during the first month.

Correspondence**Air-borne Infections**

SIR,—Your hospitable columns have latterly given space to discussions of air-borne infection, in particular to comment on the stimulating volume by Prof. O'Hara and to a status report of my own on that subject (1944, 1, 296; 2, 82). Although the desirability of ameliorating disease responsible for so considerable a wastage in time, money, and well-being would seem to be self-evident, this desirability is questioned, notably in the persuasive words of Dr. O'Hara:

"From a sufficiently detached and objective point of view it is possible to look upon the present prevalence of respiratory infection with some satisfaction and equanimity, for it is more responsible than any other factor for keeping the population ready and resistant to that greatest cold—pandemic influenza—which might otherwise be a much more frequent and deadly visitor. . . . The writer prefers to think of them [the costs] as a reasonable price paid for the preservation of some semblance of respiratory resistance, for an initial resistance to invasion may be cheaper to maintain than to dispense with, biologically as well as socially and politically. . . . Let us not be too impatient with our yearly colds: they keep us from becoming immunologically soft, as we assuredly do when we successfully isolate ourselves from them for any long period."

However, influenza virus of Types A and B are currently each being used successfully for active immunization against epidemic human influenza of corresponding type. Cross-protection is not demonstrable between Types A and B. The causal agent of pandemic influenza is unknown. The justification for assuming that the miscellaneous and miserable respiratory episodes of the winter months afford protection against pandemic influenza is therefore not apparent to the present writer. Certainly we would not do well to rely upon such haphazard means. It seems to the writer more likely, indeed, that the emergence of pandemic influenza is preceded by the appearance somewhere in the world of a mutant virus of peculiarly high communicability. In this case the prevailing conditions permitting universal dissemination of respiratory flora are less a safeguard than an invitation to disaster.

Against what, then, might we become "immunologically soft," lacking the banal respiratory infections? There is evidence that the virus or viruses of the common cold do afford some transient increase in resistance, but this does not last for most persons even through a single winter, and can hardly be regarded as of long-range value. Is it against the common bacterial secondary invaders, pneumococci, haemolytic streptococci, influenza bacilli, or staphylococci? Protection against invasion by each of these bacterial species is known to be specific for type, and fifty-odd types of pneumococci, forty-odd types of *Streptococcus pyogenes*, and at least two types of *Haemophilus influenzae* are now recognized. It is possible that a useful degree of resistance against the prevailing flora might be built up temporarily within an isolated population, such as that on a ship at sea, but in ordinary life, with innumerable opportunities for interchange of respiratory flora at work, on the way to and from work, and in homes and places of recreation, there seems to be little bacteriological or immunological basis for expecting benefit from infection. Moreover, the respiratory pathogens are not well adapted to propagation or even long persistence on normal mucous membranes. Reduction of the means of dissemination of pathogens would unquestionably entail reduction in morbidity and a corresponding reduction in carrier rate and in the prevailing prevalence of infectious agents.

Nor do relevant epidemiologic facts sustain the argument against suppression of the vehicles of respiratory infection. Rates of respiratory disease, as is well known, tend to show a lesser early winter and a greater late winter peak. The early winter peak doubtless reflects renewed exposure of a population with a diminished resistance against certain pathogens, but the peak in the late winter or early spring is characteristically higher with respect both to morbidity and to severity of complications, and this unquestionably reflects the widespread dissemination

during the winter of viral and bacterial pathogens. Finally, there is the actual record (Gafafer, W. M., "Sickness Absenteeism among Male and Female Industrial Workers, 1933-42, Inclusive," *Publ. Hlth Rep Wash.*, 1943, 58, 1250, "Sickness Absenteeism among Male and Female Industrial Workers during 1943, and among Males during the First and Second Quarters of 1944, with a Note on the Respiratory Epidemic of 1943-4," *ibid.*, in the press) showing a steady building up, in the United States at least, of rates of respiratory infection from 1938 through 1943, contrary to the long range trend. If an effective resistance were purchasable at the price of frequent infection, this should automatically check the rise in infection rates. Infection rates, on the contrary, have continued upward even at an accelerating pace under conditions in the war years. It seems unlikely, too, that abolition of water sanitation or pasteurization of milk would be advocated on the grounds that these measures make us "epidemiologically soft" with respect to intestinal infection, although T. E. Lawrence in his *Seven Pillars of Wisdom* does smile at the expense of newcomers to Arabia because they cannot drink with impunity from desert water-holes. Vaccination can keep the immunologic mechanisms in function, if necessary, more surely and more systematically than can haphazard natural infection.

"Sufficient unto the day is the evil thereof." The evils of respiratory infection are unequivocal, in my belief the means of dissemination of respiratory disease agents should be attacked wholeheartedly, uninhibited by concern over remote possibilities should we succeed beyond our hopes. In fact, what is done in the next decades to understand and control air borne infection may be taken as a significant index of how well we have learned one lesson of the war—that the broadest possible development of pure and applied science is fundamentally related to national security and well being—I am, etc.,

School of Medicine, University of Pennsylvania
Philadelphia.

STUART MUDD

Renal Osteodystrophy

SIR—Your annotation of Aug. 19 on renal osteodystrophy—the condition called renal rickets in this country—is very interesting, but omits any reference to recent work in this country. The article gives an excellent account of the condition mainly based on the important paper of Liu and Chu (1943). They found that vitamin D, although of great value in rickets and osteomalacia, was useless in the treatment of renal osteodystrophy, even when given in large doses. It has been stated by other observers that vitamin D is of no value, although Gjorgy (1928), Duker (1928), Schick (1929), Karelitz and Kolomyzeff (1932) all reported that healing occurred in their cases. We showed in 1938 that the characteristic lesions on the epiphysis was completely healed in two patients. Since then we have treated two patients with success. Sheldon (1943) has also reported healing.

It is of importance to consider why we succeeded while Liu and Chu and others have failed. Our patients were young—8 and 15 years respectively—and both showed the characteristic changes in the epiphyses. Two of their patients, aged 8 and 20, had the epiphyseal changes whilst the other three, aged 20 and over, had fused the epiphyses and showed well marked osteoporosis, and were therefore rather different. The kidney lesion was severe in our cases and comparable with those reported by Liu and Chu. The dose of vitamin D they used was 12,000 units a day, but this was given only for 20 to 30 days, although in one case it was repeated and in two cases a single massive dose of 1,000,000 units was given without any demonstrable effect. The dose we gave was 3,000 units daily, together with 15,000 units of vitamin A in the case of the youth of 15, but this dose was maintained for 16 months. During this time he grew 6 in height and the x-ray appearances improved markedly. The dose was then doubled, partly because the amount of calcium retained was not large and partly because he was growing so rapidly, this dose was maintained until his death 14 months later. The rickets had completely healed by this time. The second patient was given 6,000 units of vitamin D with 30,000 units of vitamin A for a period of 14 months, and the x-ray appearances of the epiphyses improved greatly. For the last two months of his life he was given 9,000 units of D and 45,000 units

of A, and the ulna did not show any signs of rickets on section. The diets used were high in calcium, containing over 1,200 mg a day, and the inorganic phosphorus varied from 700 to 1,100 mg a day.

The essential difference between our treatment and that of Liu and Chu is the giving of sufficient alkali to maintain the alkali reserve within normal limits. A low alkali reserve is always present in these cases, as Liu and Chu also noted. We cannot find any evidence that they gave alkali at the same time as the vitamin D, and believe that this omission was responsible for the lack of response to vitamin D during their short experiments. We did not know whether the vitamin D or the alkali was responsible, as we gave both simultaneously, but since then we have treated one patient with alkali alone, with considerable improvement in the kidney function but with no apparent change in the epiphyses.

We do not think that the vitamin A plays any direct part, though it was given to maintain the general health, and Sheldon's (1943) patient healed his rickets without being given any vitamin A. We therefore believe that vitamin D can act only when the alkali reserve is within normal limits. Liu and Chu suggest that a specific inactivation of the vitamin D is conditioned by the renal insufficiency. If this be correct the alkali may act either by improving the kidney function or by keeping the intestinal contents more alkaline. This latter condition must occur as our patients were given the equivalent of 12.4 and 20 g of sodium bicarbonate daily. It is said that vitamin D increases the H-ion concentration of the gut and so enables the calcium to be absorbed, and if this is the case it would explain why we found it necessary to give such large doses of vitamin D.

The experiments which Liu and Chu made with dihydroxycholesterol (AT 10) are very interesting. They found that the absorption of calcium was much improved in two cases, although no alkali was given at the time. It would be most interesting to know whether the function of the kidney improved during this period and whether the giving of alkalis hindered or helped the absorption of the calcium.—We are, etc.,

Dentition and Diet

SIR—I was much interested in the article on the improved dentition of London school children by May Mellanby and Helen Coumoulos in the *Journal* of June 24. I note that no mention is made of the reduced carbohydrate intake in the form of sugar, sweets, cakes, etc., which to my mind is a most important factor. It appears to me that the improvement of the dentition of these children is due not so much to the changes in the feeding habits mentioned but rather to the decreased carbohydrate intake as a result of wartime rationing of sugar, sweets, cakes, etc. Many prominent dental research workers both in England and in America will, I think, agree with this view.

Extensive dental surveys of many thousands of children in South Africa have indicated that caries increases rapidly among both European and non-European children when the sugar, sweet, cake, etc., intake is increased. The difference between the caries experience rate of children in the north west Cape, where the staple diet is mutton and bread, and that of the children in the coastal area of Knysna, who eat sweet potatoes, bread, and very little meat, is outstanding. In the former case the caries-experience rate is 40%, and in the Knysna area it is 99%. Mention must also be made of the significant fact that the fluorine content of the drinking water in the north-west Cape is high, while in the Knysna area practically absent.

The report on the South African dental surveys has been published by the Union Health Department, and a copy is enclosed for your information—I am, etc.,

T. OCKERSE
Dental Health Officer, Union Health Department,
Pretoria.

Bleeding Gums in R.A.F. Personnel: Value of Ascorbic Acid

SIR,—We are sorry that in our reference to the early descriptions of scurvy in our article (Aug. 19, p. 239) we did not make it clear that we were referring to uncomplicated scurvy. As Dr. Glazebrook points out (Sept. 9, p. 353), Lind states that "when a person has had a preceding fever or tedious fit of sickness" the gums may be first affected. These conditions, of course, did not apply to the healthy R.A.F. personnel examined by us. In the description of ordinary scurvy given by Lind, as well as more recently by Hess (*Scurvy Past and Present*, J. B. Lippincott, 1920, p. 176), the gums are specifically stated to become sore and to bleed after the onset of other signs and symptoms (change of complexion, listlessness, breathlessness, pains in joints). McMillan and Inglis, in their recent excellent description of fifty-three cases of scurvy (Aug. 19, p. 233), also say that "bleeding gums were noted on eight occasions, being present only in association with gross changes elsewhere," although these authors apparently did not apply friction to elicit this sign.

The "apparent success in treatment with ascorbic acid" often occurs in experiments with no adequate controls, and our explanation of this apparent success obviously could not apply to the experiment of Roff and Glazebrook, where controls were examined. The condition of bleeding gums with "sponginess," which we noted frequently, seemed, however, to be identical with these authors' "gingivo-stomatitis." We considered whether our results differed from theirs because of the different intake of ascorbic acid, but in some of our experiments the difference was small. (More recent surveys on R.A.F. personnel over-seas have shown no increased incidence even when the intake was as low as 9 to 16 mg. daily.) Because of the different results achieved in two apparently similar experiments we were careful to limit our conclusions to R.A.F. personnel and to state that "this does not exclude the possibility that other subjects living under different dietary conditions might benefit from treatment with ascorbic acid." Is this English sufficiently plain?

The objections raised to our article by Dr. E. P. Evans (Sept. 2, p. 321) can hardly be taken seriously. We and others have carried out numerous saturation tests in which ascorbic acid, administered by the method described in our article, has always produced "saturation" and then appeared in the urine. This could scarcely have happened if the ascorbic acid is destroyed in the mouth or is not absorbed from the alimentary tract, as postulated by Dr. Evans.

Dr. Malik (Sept. 2, p. 328) asks what we mean by "dummy" tablets. The tablets used were made of starch flavoured with tartaric acid, which so far as we know has no effect on any dental disease.—We are, etc.,

W. P. STAMM.
T. F. MACRAE.
S. YUDKIN.

Fracture-dislocation of the Astragalus

SIR,—Squad. Ldr. James's paper (Sept. 16, p. 372) appears misleading in several important respects.

The injury described and illustrated is not a fracture-dislocation of the ankle; it is a fracture of the neck of the astragalus associated with a subastragaloid dislocation, and a complete posterior dislocation of the body of this bone. Nor can this accurately be described as "typical," in that it is only one of the various types of fracture-dislocations of the astragalus. (Ninety-seven such injuries were treated in R.A.F. orthopaedic centres during two years of war; of these only seventeen were of this particular type. R. Watson-Jones, *Fractures and Joint Injuries*, Livingstone, Edinburgh, 3rd ed., 1944, p. 825.)

Treatment of this injury is certainly "to be looked on as urgent." If unreduced, pressure by the displaced body produces necrosis of overlying skin within 48 hours, the skin breaks down, and the body is extruded as a sequestrum. Once the skin has started to break down there is no option but to remove the body, if it is not already extruded, and to immobilize the limb in plaster until infection has subsided and the wound has healed, taking care to maintain contact between the lower end of the tibia and the neck of the astragalus—i.e., to prevent the whole foot slipping forward.

If seen within a few hours of injury, however, I cannot agree with Squad. Ldr. James's assessment of the relative values of the various methods of treatment available. Closed reduction is admittedly not easy, but it is certainly feasible in many recent injuries. If reduction by manipulation proves impossible I have used skeletal traction by an os calcis pin, and inserted a second pin into the displaced body to rotate and guide it back to its socket. This method has since been described by Watson-Jones in his book already referred to (p. 835) and by W. D. Coltart in a paper read to the British Orthopaedic Association, Oct., 1943. Operative reduction should only be employed as a final resort. Removal of the body of the astragalus is preferable to astragalectomy. Not only is the immediate result better but subsequent arthrodesis, if necessary, is easier if the head of the astragalus is *in situ*.

Regarding the relative values of astragalectomy and tibio-calcaneal fusion, in the series referred to above, "the most striking inference was that the results of astragalectomy were uniformly bad and the results of tibio-calcaneal fusion surprisingly good" (Watson-Jones's work, p. 840). As the astragalectomies in the series were performed by a number of different surgeons, it seems unlikely that Squad. Ldr. James's suggestion that "the depreciation of this operation is in large measure due to inadequate surgical technique" is correct.

It is suggested that immediate arthrodesis is the treatment of choice. This would entail arthrodesis of both ankle and subastragaloid joints. Reduction of the dislocation would first be necessary, and operation would be further complicated by the presence of a fracture of the neck of the astragalus. To attempt such a sweeping procedure in the face of the gross bruising and swelling which is always associated with these injuries appears to me to be unduly resolute surgery, even in these days of chemotherapy.

This war has provided an opportunity for the study of a larger series of these very difficult and complicated injuries than has ever before been collected. The conclusions reached have been very clearly expressed by Wing Cmdr. Coltart and Mr. Watson-Jones. It seems a pity that a paper controverting so many of these conclusions should refer to one case only.—I am, etc.,

J. R. ARMSTRONG.

Ely.

Fractures of the Carpal Bones

SIR,—The article on fractures of the carpal bones by my old teacher, Prof. H. A. Harris (Sept. 16, p. 381), was long overdue, and I sincerely hope that it is widely read and thoroughly digested by all those in the profession. One has too often seen these "minor" injuries of the carpal bones entirely missed, and only diagnosed many months later when the damage has been done and cannot be undone—namely, an osteo-arthritic wrist. This is partly due to inexperience and partly to the too infrequent use of radiography in diagnosis. Also it is the oblique view which is so often the one that shows up these "fake" fractures, and so often the clinician omits to have an oblique view taken. It should therefore be taken, as well as the lateral and A.-P. views, as routine in all cases where bony injuries to the wrist are suspected. Prof. Harris states that in Colles's fractures the ulnar styloid is also sometimes fractured. It is generally considered, however, that the ulnar styloid is always fractured in a Colles's fracture, although the lower end of the radius is often fractured without involvement of the ulnar styloid.

It might also be timely to state here that a very similar state of affairs to that which Prof. Harris pointed out as existing in the wrist exists in the ankle. "Flake" fractures often occur at the proximal or distal attachments of the deltoid ligament of the ankle-joint. Either the joint is not x-rayed or the radiograph is misinterpreted, and the patient is sent hobbling out as a "sprained ankle." The result of this is prolonged disability. These flakes are sometimes extremely difficult to see, and in cases of doubt the treatment should consist of the immediate application of a walking-plaster. The diagnosis of these fractures is made much more difficult by the presence of an effusion, which makes early x-ray most important. In cases of unavoidable delay one should therefore not omit to apply a pressure bandage and an efficient splint with the leg elevated.—I am, etc.,

B. S. SKINNER.

Laryngeal Spasm

SIR.—Fl. Lieut. Heyworth states (Sept. 16, p. 385): "My impression is that once severe [laryngeal] spasm has been allowed to develop, nothing can be done until the false and true cords have relaxed." I can assure him that it is unnecessary to wait until the patient is "pulseless, black, and virtually on the point of death." I have never yet, during a good many years' experience, met a laryngeal spasm which could not be dealt with by intubation with a gum-elastic catheter (urethral or as supplied for purposes of anaesthesia is equally suitable, of about 7 mm. diameter for adults). The smooth rounded end of such a catheter will pass between cords in spasm easily, quickly, and without trauma. I always have several sizes handy when anaesthetizing. As the American gentleman is alleged to have replied when asked why his hip-pocket contained a gun: "I don't need it often, but when I do I need it darned quick."—I am, etc.,

London, N.W.11.

STEPHEN COFFIN.

Trypanosomiasis treated with Pentamidine

SIR.—After reading Lieut.-Col. R. R. Bomford's article in your issue of Aug. 26 I feel the time is opportune to add a comment on the place of pentamidine in the treatment of West African sleeping sickness in general, since late as well as early cases may be met with in this country among Europeans returned from West Africa, and some articles which have appeared may have conveyed the impression that pentamidine is the drug of choice. No reflection is intended on Lieut.-Col. Bomford's article, in which he specifically referred to early cases, though in point of fact the case he describes had passed the first stage.

I am at present on leave from Sierra Leone, and can only quote the literature from memory; but I have before me records of nearly 2,000 cases of sleeping sickness treated with various drugs and combinations of drugs, including pentamidine. These cases were re-examined more than a year after treatment; over half were lumbar-punctured before treatment and the cells counted, and in about half both cells and total protein were enumerated at the final examination. They included 192 cases treated with pentamidine and 55 with propamidine. The dosage of pentamidine varied between 8 and 12 daily doses of 50 to 100 mg. No appreciable difference in curative effect was noted between the higher and lower dosages, and propamidine produced very much the same results as pentamidine.

In brief, in early cases with a normal C.S.F. cell count the curative value of pentamidine proved to be only slightly, if at all, inferior to that of a course of antrypol followed by tryparsamide (total of 8 or 9 doses), but the toxic effect of the drug itself was less than some of the antrypol-tryparsamide combinations. Incidentally, such toxic effects are likely to be less pronounced in Europeans than in undernourished Africans. For in-patient treatment pentamidine also has the merit that the doses can be given daily.

In late cases, however, pentamidine showed to great disadvantage, and where the C.S.F. count exceeded 100 cells per c.mm. before treatment about 45% of the patients died within a year, and of the survivors about 75% had definitely abnormal spinal fluids at the time of examination. The corresponding figures after antrypol plus tryparsamide were only about 13% of deaths and 20% of abnormal fluids. Comparing the general run of cases as met with at all stages, 93.5% appeared to be cured after the best combination of antrypol and tryparsamide, but only 73% after pentamidine or propamidine. It is the general experience also of workers in Nigeria, the Gold Coast, and the Belgian Congo that pentamidine is useful in early cases but of very little value once the central nervous system has been affected. In the Sierra Leone series the dividing line lay around 10 to 15 cells per c.mm.

These findings indicate that it is unjustifiable to treat any case of trypanosomiasis with pentamidine alone without first carrying out a lumbar puncture, and that it is still unjustifiable so to treat it if the C.S.F. shows more than a very slight degree of abnormality. In a small-scale trial in Sierra Leone with 53 cases treated by a combination of 5 doses of 100 mg. of pentamidine and 5 of 2 g. of tryparsamide, given concurrently, the results were excellent in late as well as early cases. Either the pentamidine and tryparsamide were given together at

5-day intervals, or the tryparsamide was given at 5-day intervals while the pentamidine was given daily, starting the day after the first tryparsamide. In this way the whole course of treatment was reduced to three weeks. There were no toxic effects beyond the transient symptoms frequent after pentamidine, and the combination appears promising; but the common type of trypanosomiasis in Sierra Leone, even when symptoms are severe, is rather unusually amenable to treatment, and further trials elsewhere are indicated before an authoritative pronouncement can be made. In the meantime it would seem best to continue to use the well-tried combination of antrypol and tryparsamide as a routine for cases with any involvement of the central nervous system.

It is worth mentioning that most of the results published on treatment with pentamidine lose much of their value owing to the fact that the cases have not been followed up long enough. Experience in Sierra Leone has shown that it is not possible, within a year after treatment, to be certain whether cure has been effected, and cases have been met with whose C.S.F. cell count has been normal at six months but has risen again later. Conversely, some cases still showed raised counts at six months which have returned to normal in a year.

The dosage given by Lieut.-Col. Bomford—repeated doses of the isethionate up to the equivalent of nearly 4 mg. of pentamidine per kilogramme—is very high, and most workers do not exceed 2 mg. per kg. when daily doses are given. Though one should exercise caution in applying results obtained on animals directly to man, it is worth recalling that Van Hoof found repeated doses of about 4 mg. per kg. lethal to guinea-pigs, and Daubney and Hudson observed delayed poisoning after pentamidine in only moderately heavy dosage in cattle. In default of sufficient observations on the maximum tolerated dosage in man, such results indicate the need for great caution in employing such heavy dosage, and there is no evidence of which I am aware that anything is to be gained by it in sleeping sickness, though it may be otherwise in kala-azar.

Since writing the above I have come across the paper by Allen, Burgess, and Cameron (*J. Path. Bact.*, 1944, 56, 217) on the toxic effects of propamidine. They found the lethal dose (LD50) of the dihydrochloride to be 10 mg. per kg. for the goat, 15 to 20 mg. per kg. for the rabbit, and 10 mg. per kg. for the guinea-pig. The isethionate appeared to be only slightly less toxic. One may expect considerably smaller doses to be lethal if repeated daily, and these results emphasize the need for caution in the dosage of the closely allied drug pentamidine in man.—I am, etc.,

Wootton Courtenay, Minehead.

R. D. HARDING, D.M.

War Malaria and its Treatment

SIR.—In the letter on war malaria and its treatment (Sept. 9, p. 351) we read: "It is necessary to continue with small doses of quinine by the mouth—10 to 15 gr. daily—for three weeks or longer. I certainly believe that small doses of pamaquin—0.04 g. daily—in addition to quinine, also aid in preventing relapses." Did the writer intend that pamaquin—0.04 g. daily—should be administered for as long as the quinine—namely, three weeks—instead of the usual five to six days? He later goes on to say that "quinine (30 gr. daily) for two days, mepacrine (0.3 g. daily) for five days, followed by pamaquin (0.03 g. daily) for a similar period, appears to be inadequate."—I am, etc.,

Kilmarnock.

H. M. OWEN.

Specialties and Diplomas

SIR.—There must be diversity of view about the problems of postgraduate medical study, but I think that Major-Gen. Max Page's kindly dissent from some of my views is based upon misunderstanding, for which a lack of clarity on my part may be responsible.

Of course I do not include the F.R.C.S. or the M.R.C.P. among the mushroom growth of specialist diplomas, though I am not persuaded that they are noticeably concerned with the basic sciences of medicine. Also, I have not advocated the abolition of the special departments of general hospitals, but rather the necessity for conducting higher studies and research in certain branches of medicine in special hospitals and schools. I have served on both special department and

special hospital, and believe that the functions of the two are different and cannot be merged in the special department of the general hospital, large or small. No one disputes that all branches of medicine are but parts of a whole, but the argument has no bearing upon the expediency of devoting special institutes to some of them. It is not for me to argue the status of dermatology as a special branch of medicine, but the notion that the skin is just the wrapping of the human parcel, occasionally betraying the disquiets of its contents, does scant justice to a very complex organ, and I should have thought that few branches of medicine more urgently required intensive study in a special institute.

There is, however, a misapprehension in his letter that is none of my making, as when he suggests that had those who have worked in the National Hospital shown themselves as interested in disorders of the functions, as in those of the structure, of the nervous system, medicine would have benefited even more. This is a surprising comment upon the hospital of Hughlings Jackson, Ferrier, Horsley, and others since their day whom I need not name. Surely, too, the essence of neurological diagnosis is the study and analysis of disorders of nervous function, from which alone, clinically, can the seat and nature of structural disorder be determined. Casting round in my mind for some explanation of this false idea of the history and nature of neurology, it occurs to me that Major-Gen. Max Page has confused two very different notions—namely, physiological and psychological disorder—how different the psychologist will be eager to tell him. Even so, I venture to suggest that he is rather out of touch with the facts. Thus, in this war as in the last, major contributions to the problems of psychological stress in air-crews have come from distinguished members of the hospital staff.

However, in so far as he is in favour of the still more intense study of psychological medicine in the hospital, I am with him. Up to date, as a leading psychiatrist has stated before the Goodenough Committee, "the accurate knowledge possessed by psychiatrists of mental disorders and their treatment is still of modest dimensions," and no one can doubt that neurology has an important contribution to make to the subject.—I am, etc.,

London, W.1.

F. M. R. WALSH.

SIR,—Conversations with medical colleagues have convinced me that Dr. Walshe's article (Sept. 2, p. 297) must rank as one of the most candid, stimulating, and reasoned essays of recent years. Already it has moved some of the senior members of the profession to reply. The article is extremely opportune, and merits full discussion from all points of view. It is as one of those who did not, at the appropriate time, as Dr. Walshe says, "acquire those alphabetical adornments that we have asked of those to whom we have offered opportunities in consulting and academic medicine" that I lay a claim to take part in the discussion.

With my due respects to Mr. Max Page (Sept. 16, p. 384) I think Dr. Walshe presents the case for and against postgraduate diplomas very fairly and reasonably. Is not the F.R.C.S. a postgraduate diploma? Talking of this and the M.R.C.P. Mr. Max Page says: "These diplomas are generally accepted as evidence of a man's sound training in the basic sciences and his subject." With certainty, much better evidence could be obtained from a detailed inquiry into his work and interests from school upwards. Further, Mr. Max Page remarks: "Few would regard them as more than that." May I respectfully suggest that that is not the opinion of the general public, local authorities, or even the majority of the medical profession.

Many agree with me that we might gain something from the adoption of Continental methods. Surely five years' suitable postgraduate experience could constitute not merely evidence but proof of a person's suitability or otherwise for consultant or academic medicine. A good surgeon needs a deft pair of hands, a suitable temperament, and a sensitive conscience. An examination track mind is not necessarily an asset.

I understand that the regulations for the F.R.C.S. have been altered recently. There may be some good reason that I, for one, do not know of, but it would rather suggest that the "oldest and best established" were not, after all, the best. In spite of the fact that it was not an essential for a candidate

for the F.R.C.S. ever to have performed a major surgical operation, nevertheless the possession of that diploma is a *sine qua non* in most hospitals for appointment to the surgical staff. Thus, whatever a person's ability and experience he is barred from being an applicant if he cannot show proof in the way of a diploma that he has been a house-surgeon. Perhaps Mr. Hamilton Bailey will forgive my quoting from the preface to his book on *Emergency Surgery*. "I had now climbed another rung, and found myself on the junior honorary staff of a teaching hospital, with plenty of time to write, but with hardly any emergency operations to stimulate me to do so. Commencing to form the early chapters, I came to the conclusion that my experience was still insufficient, and it was largely on this account that I descended the surgical ladder and once again became a resident surgical officer, this time at a very large hospital in Birmingham. Here I was afforded unique experience in emergency surgery." Due reflection on these comments must leave some of us apprehensive, particularly when the subject of teaching is up for discussion.

Dr. Walshe's cryptic reference to original articles is very much to the point when he states: "And the author, especially if he be young, who ventures daringly to attempt some generalization or synthesis of his findings with those of other workers is in danger of having his contribution declined. Having suffered thus, I am bound to complain that this state of affairs is beyond an average comprehension. Any sincere worker would welcome any criticism of his observations and conclusions provided such criticisms are supported by appropriate evidence. And if there remains only a small contribution to learning, surely the profession should be glad of it.—I am, etc.,

J. SHIRLEY CALVERT.

Wembley.

Present-day Medical Education

SIR,—This is the view-point of a product of present-day medical education. I cannot speak as a representative of the views of young practitioners, because we have no uniform views any more than experienced general practitioners or clinical teachers have such views. I cannot accuse my teacher of hiding behind laboratory results. They knew what they wanted the student to do: they wanted him to master the technique of interrogating and examining a patient and to learn to think. From pre-clinical times it was drilled into us that we were going to reach our conclusions via our eyes, our ears, and our finger-tips. The wards, the out-patient departments, and the practical classes were stressed as far more valuable than the systematic lectures. Pity the man who, when asked how he would diagnose a condition, replied first of all with a laboratory examination!

And what about the finished product? Personally, I qualified less than a year ago, and still feel unfit to attempt large classes of patients such as are met with in general practice. Four or five months as a house-surgeon and the same period in the Army have brought home to me two outstanding facts: the number of cases I cannot diagnose, and the even greater number which I cannot treat to my satisfaction.

Over half of these failures can be laid at my own doorstep: ignorance, insufficient care or patience, and sometimes the easy classification of a case as "functional." This still leaves a large number unaccounted for. Some of these could have been successes given different medical training. Too little time is paid to treatment, especially local treatment, and too little attention to the diagnosis and prognosis of those cases with symptoms but no signs. How many of my contemporaries can dismiss a patient with the confident assurance that there is nothing wrong with him?

The cure, in my opinion, lies after the final examination rather than before it. A year's compulsory hospital residence? Certainly; and let there be sufficient emphasis on out-patient work. But still more is a year's apprenticeship in general practice required for all doctors, no matter what they may eventually tackle. The training of efficient G.P.s is more difficult, and promises bigger dividends in national health, than the training of specialists. I have heard specialists regretfully admit that they have had too little general training; but I have yet to hear one say that he spent too long a preliminary period in general practice.—I am, etc.,

H. A. LANG.

Observation in the Student's Training

SIR—In his most interesting article (Aug 26, p 284) Dr Ft Robinson emphasizes that the modern student, instead of asking himself what he actually sees, asks himself what he should see. This outlook is encouraged at the present time by the variety of labels attached to diseases and syndromes. In many schools the student who can recite parrot fashion the varied nomenclature of such diseases as thrombo angitis obliterans is looked upon with favour. Naturally his class-mates endeavour to emulate him. Until the end of the Dark Ages almost all academic thought centred on the teachings of the ancients. While Plato and Aristotle were studied intently the emphasis was on the purely intellectual interpretation of these men's work, and their conclusions were considered as the be all and end all rather than as indications for further work, both observational and theoretical. With Galileo, Newton, and their contemporaries we witnessed the birth pangs of the age of accurate observation. At the present time we seem to approach the twilight of this age.

Whitehead has divided the scientific approach into three stages: the stage of description, the stage of classification, and the stage of measurement. At the present time, in the medical field, some workers are concerned with the first stage, some with the second, and many with the third. For results to be of value and not subject to almost immediate contradiction, careful and full observation is of supreme importance at each stage.

As a background to all this comes the question of interpretation, and for this sound reasoning—inductive and deductive, as emphasized by Dr P T Macdonald (Sept 9, p 354)—is of paramount importance. Dr Macdonald does not seem to appreciate, however, that a mighty intellect working on wrong observations may be made much more of a hindrance than a help. Much importance is attached to the conclusions of the great minds, but these are only of value in so far as they are based on accurate and painstaking observation. At the present stage of medical development we are far from being able to dispense with those relatively neglected but very useful instruments: the human eye, the human ear, the human fingers and the human nose. In how many, alas, these are the eyes which look but do not see, the ears which listen but do not hear, the fingers which touch but do not feel, and the noses which sniff but do not smell!

The reason for the accumulation of undigested facts is that the present generation is being trained on absorptive rather than observational lines. As time goes on, many of these undigested 'facts' are found to be fallacies. The trained observer can spot a fallacy much more quickly than the student who can recite large portions of Cunningham, Gray or Price verbatim, but who is often incapable of recognizing before him the conditions with whose theoretical aspects he is well acquainted. I believe Dr Macdonald would agree that Michelangelo, Leonardo da Vinci, Shakespeare, Dickens and (more near our own time) Rutherford, Lister, and Elliot Smith were all shrewd observers, and that no small amount of their permanent contribution to knowledge, thought, and art was the result of painstaking observation.

The teaching of accurate methods of thought is more difficult than the teaching of observation—as witness the powers of observation of most young children. That these studies are complementary and not antieconomic would be admitted by most. Let us start our reforms with emphasis on the powers which tend to atrophy, but not forgetting the importance of the powers we can acquire—namely those of accurate thought—I am, etc.,

JOHN GRIEVE
Squad Ldr R.A.F.V.R.

Limitations of Current Medical Training

SIR—In his letter on limitations of current medical training (Sept 16 p 352) Dr Robinson restarts the old argument of old methods versus the new, and although there are some elements of truth most of the remarks can be criticized.

It is quite true that in teaching hospitals many of the pathological tests which are performed are quite unnecessary, but in most of the cases the diagnoses have been made and the laboratory tests are done merely to show the student the com-

plete picture of the disease. The young doctor who goes into practice thinking that diagnoses can only be made by tests rather than by examination of the patient is the exception and not the rule.

The third and fourth paragraphs appeal to me, being an unfortunate R.M.O. He states that lobar pneumonia was diagnosed on the wrong side due to laboratory findings. I should be interested to know what investigations gave one the diagnosis of lobar pneumonia except an x-ray examination, which would hardly give the wrong side. He then states that both the patients, being dosed immoderately with sulphapyridine, developed lung abscesses, this not being unexceptional. I feel that lung abscesses following lobar pneumonia are very exceptional, and I should like to know his reasons why immoderate dosage should cause such a condition. As an R.M.O. one so often reads in doctors' letters that sulphonamides have been given—tab 2 t.d.s.—it being very unusual to find that it is the house officer who gives the wrong dosage.

As for the typical remarks about cardiac murmurs, at my London teaching school (and I do not believe that this is the only exception) we were taught the relation of cardiac murmurs to the pathology of the cardiac condition, but it was stressed that murmurs were not the be all and end all of cardiology.

In the last but one paragraph the house officer gets it in the neck again. It was stressed throughout the whole of his teaching that he should not, if possible, reduce a dislocation without an x-ray examination, not because he is unsure of his diagnosis but because of concomitant fractures being unrecognized and the intricacies of the law courts.

To finish, I should like to know how many old practitioners with the aid of physical signs can differentiate between 75% and 100% haemoglobin, this being of importance in a case of pernicious anaemia where the threat of subacute combined degeneration is not always so far distant. I feel that 265 blood counts could just possibly be performed on such a case over many years, but to say that this is a typical example of modern methods is, I feel, a little over-exaggerated, as is also, I think, the whole of Dr Robinson's letter—I am, etc.,

High Wycombe Hospital.

RICHARD STURTON

SIR—I should like to make a few comments on Dr Henry Robinson's letter.

I agree with his remarks about specialization at an early age. I was swept up by the Army six months after qualifying and was quite unable to start on the road to specialization and am duly grateful. I now see all sorts of complaints and am learning the great importance to the individual of the trivial. But when he starts to criticize the abilities of the young doctor he paints a picture of unmitigated gloom, only relieved by touches of sheer balderdash. I have never seen or read before of lung abscess as a direct result of sulphapyridine overdose. What is the scientific proof for this amazing statement? It sounds like pure intuition on the part of the "old physician". In my experience it is far commoner for sulphapyridine and other sulphonamides to be given in too small rather than too large quantities.

His remarks about the diagnosis of cardiac disease are true of physicians of all ages. But we were always taught that a murmur gives no indication of the efficiency of the myocardium but it may give an all-important clue to the aetiology of a given case of cardiac failure and thus have a very important bearing on prognosis.

It was also always insisted by my teachers that we should take a full history and make a thorough examination before we ever thought about laboratory tests. X-ray and other examinations not forgetting those carried out in the "Temple of Verities," the post-mortem room, are an essential check on one's physical signs. Those who use these aids frequently and intelligently find out how often they are wrong and learn to do better in the future. Those who do not, remain in blissful ignorance and are a menace.

Lastly I should like to express a word of admiration for the persistence of the poor fool who carried out 265 blood counts on one individual. Perhaps he discovered some important variations in the healthy blood picture, which I hope he will duly publish—I am, etc.,

I S STADDON

Refresher Courses for the G.P.

SIR,—Dr. Walshe in his article (Sept. 2, p. 297) looks to the replanning of the conditions of medical practice rather than the refresher course to help the practitioner keep abreast with the advancement of medicine. Unfortunately it is doubtful whether such an ideal state of affairs can be brought about in the near future, and so the following is suggested as an alternative method of achieving the same result.

General practitioners, who naturally have little time to spare for refresher courses and little inclination to upset their regular work, do find they have an occasional hour or two to spare on some afternoons in the week. Surely postgraduate study could be arranged to coincide with these spare times? The type of study that appeals to the practitioner is that which most nearly approaches his own work—i.e., a clinical round in a hospital. Therefore, if all the hospitals in any area held a clinical round for practitioners, each on different afternoons in the week, when members of the staff demonstrated medical and other cases at the bedside, the practitioner living in a large city like London would always find a local hospital where a clinical round was being held at the time he happened to be free.

Regular instruction of this nature throughout the year is the best method of postgraduate training, and at the same time leads to better co-operation between practitioners and hospital staffs. The benefits of such a plan to all concerned were obvious to those who attended such a weekly round held before the war at St. Mary Abbots Hospital, L.C.C., Kensington, by the great initiative of the medical superintendent, Mr. James Carver.—I am, etc.,

London, W.8.

H. STEPHEN PASMORE.

Cancer Clinics: Beware

SIR,—While clinics have their uses, they can be overdone. In the case of venereal disease they serve well, but there the symptoms are usually unmistakable. It would be the very reverse with a disorder so protean in form as cancer, in which the early stages are apt to arouse but little suspicion of their sinister significance.

The public is painfully aware of the hideous later stages of cancerous disease, but knows little of its inception. Yet often in the early stages it is curable. But will the cancer clinic get patients in their early stages? No! since the patient does not recognize that he has cancer, and the idea of consulting a cancer clinic will never enter his head. Even if his suspicion is aroused, he will be inclined to shun a place labelled "Cancer Clinic." Finding something wrong with himself and wanting a remedy, the patient naturally resorts to his general practitioner. Therefore he is the man to make responsible for diagnosis. When the family doctor is fully alive to his responsibilities and maintains full competence in diagnosis the patient stands the best chance of early detection of a cancer. Having known his patient previously, the doctor can view complaints in their proper perspective, which makes for quick and sure diagnosis. Moreover, the family doctor, deprived of such an important function, would lose interest, and his proficiency in diagnosis would deteriorate. Already rival services, such as infant welfare, school, and industrial clinics, tend to diminish his influence.

Not only in diagnosis but in psychology the doctor at a cancer clinic is at a disadvantage. The family doctor knows his man and the tactful way of dealing with a solemn and delicate situation. To one he is candid, to another he may hint at possibilities, while with timid or neurotic folk he excludes the slightest reference to cancer. Thus he wins the patient's confidence and willing co-operation. Once diagnosed or suspected, the case is directed to the appropriate consulting specialist for confirmatory opinion and treatment.

As already shown, special clinics dotted about the country are of little practical value in this campaign, as but a few of those for whom they are intended would avail themselves of the service. On the other hand, they would certainly do harm by initiating or fostering thoughts of the disease in those inclined to a cancerous obsession. Already cancerophobia is notorious. The existing machinery clearly contains the elements for a successful campaign—all we need is more of it. In regard to the present shortage, the bald facts are that the uninsured public can't afford their doctor, and he can't afford the time. Patients won't incur expense for a slight illness. Yet the

tantalizing fact is that operating early offers the one great chance of cure. The doctor's difficulty is that he has too crowded a surgery, and cancer calls for detailed study of symptoms and deliberate examination in adequate space, light, and warmth. Now, however, the Government promises to remove the financial handicap by a national health insurance scheme for every man, woman, and child. But money alone cannot provide the much-vaunted first-class service for all. We are bound to wait for the training of personnel. Time—7 years minimum—is needed to double the meagre ranks of the profession, just as time was required before we could convert our inadequate Air Force into a potent one.

Once the diagnosis is established and treatment arranged a third requisite remains. The case must be pursued throughout the patient's life. This is necessary to detect possible recurrence promptly and nip it in the bud, to observe the effect of treatment, and for statistical study of the disease. The general practitioner is the one most interested, and he can readily make regular observations. A special supervisory department of the public health service would be responsible for collecting official records and statistics, and would ensure that regular reports reached its office. It would be compulsory for the general practitioner to send returns annually or as often as required and to direct the patient for a consultant's opinion as occasion demanded. From the mass statistics compiled conclusions of far-reaching significance would emerge. Such a perfect follow-up system would ensure that the doctor's interest was maintained and would give the patient full confidence and satisfaction.—I am, etc.,

Bristol.

A. WILFRID ADAMS.

Lay Psychotherapy

SIR,—By way of illustrating Dr. D. Stanley-Jones's admirable letter (Sept. 2, p. 322), may I state briefly what is being done by one small body to provide doctors with skilled psychotherapeutic auxiliaries? The Guild of Pastoral Psychology was founded some years ago by a number of doctors and clergymen who felt a growing double need: among doctors, busy and untrained in psychotherapy, for workers who could help patients with personality disorders as distinct from definite mental illness; and among clergymen and teachers for sound guidance in the principles of psychology, to enable them to do their own life-work more effectively. The Guild's policy is to explore the wide common ground between psychology and religion, and its publications now cover a very respectable field. It promotes lectures and study groups, and has made a start with the difficult and delicate task of instituting a higher qualification. A "Fellow" must, unless for quite exceptional reasons, be a doctor, a clergyman, or a qualified psychotherapist; he must have passed a stiff written examination, had a thorough personal analysis, and trained under expert supervision at probation work, psychiatric out-patients, or some other recognized form of practical social psychology. Candidates are very sparingly hand-picked by the executive committee. A Fellow may not display his fellowship as a qualification. The Guild sets its face against creating a class of non-medical persons who would conceive themselves qualified to practise quasi-medical psychotherapy. It considers that any minister who wishes to practise professionally as a psychotherapist should conform to the standards laid down by recognized schools for lay psychotherapists. Its policy is to co-operate with medical practitioners and help them by all possible means in the difficult days which lie ahead, when neurosis will be rife and those who can cope with it will be few and overworked.—I am, etc.,

London, S.W.19.

D. H. KITCHIN,
Hon. Treasurer, Guild of Pastoral Psychology.

Mass Radiography

SIR,—Your reprint *re* mass radiography in the *Journal* of Sept. 9 (p. 350) shows a desire on the part of the Ministry of Health to retain mass radiographic procedure in their own hands, with no departure from the particular method and apparatus they have sponsored. Question definitely arises whether the method they have selected is the best, and, unless this is the case, use of alternative methods should not be prevented by official disfavour.

ANOREXIA

*Stimulate appetite and improve nutrition with **BEMAX** ★*

Vitamin B₁ is specific in the treatment of deficiency anorexia. Conveniently taken at breakfast, Bemax provides vitamin B₁ in abundance, together with an appreciable amount of first-class protein.

Improvement of appetite quickly results, with a progressive intake of body building and protective factors from other sources.

**PHILIPS
MOBILE 'D'
DIAGNOSTIC
X-RAY UNITS**

This fine 90/30 Mobile X-ray Unit, ideal for ward use and for emergency purposes, is widely recognised as the foremost equipment of its class. Modern in design and conception and manufactured in large series, it incorporates numerous outstanding technical advantages which are described in full in publication XMI, available on request. In radiographic performance the MOBILE 'D' is superb and, above all, it is thoroughly reliable. Authorised purchasers will find this equipment a highly satisfactory investment. Enquiries are invited.

A LOGICAL DEFENCE AGAINST COMMON COLD

⊙ A logical—and successful—method of preventing the common cold is to stimulate natural powers of resistance by immunising with Cold Dissolved Vaccine *Glaxo*. The discomfort and ill health from the common cold is caused by the secondary bacterial infection of the mucosa, and Cold Dissolved Vaccine contains all the bacterial strains commonly responsible.

A course of Cold Dissolved Vaccine *Glaxo* provides protection in many instances, and in others the severity of the attacks is greatly reduced.

COLD DISSOLVED VACCINE *Glaxo*

In 5 cc. and 25 cc. rubber-capped bottles.

CARBACHOL

M & B

has a similar, although more powerful action than the acetyl-choline group, being a parasympathomimetic agent with additional nicotinic action on the autonomic ganglia. It has little action on the pulse rate or blood pressure.

CARBACHOL M & B is of particular value in the treatment of post-operative or post-partum urinary retention, as well as in the treatment of peripheral vascular vasospasm, as in Raynaud's disease or thromboangiitis obliterans. It has also been used with effect in cases of ozoena and glaucoma, by local application in both cases.

In an editorial, *Radiology* (1942, 38, 498) discusses the relative value of 14 in \times 17 in films (12 in \times 15 in films are more commonly and economically employed in Britain), 4 in \times 5 in films (as employed in the U.S.A. in mass procedures), and 35 mm films as employed in this country by the Ministry. This editorial summarizes that full size films are the most accurate, 4 in \times 5 in films next, and 35 mm films 'should also be considered, but do not deserve such a high rating as the other two.' Kerley (*Brit J Radiol*, 1942, 15, 346) states, "Miniature radiography does not compare in detail with the full size picture, hence the method is restricted to sifting cases of comparatively gross disease." Supe (*Fort a d Geb d Roentgenstrahlen* 1940 62, 145) on the basis of 25 000 cases of miner's pneumonokoniosis considers the fluorographic method as unsatisfactory for the study of asbestosis. Briley (*Radiology*, 1942, 39, 306), having used normal and 4 in \times 10 in stereoscopic films for examination of U.S.A. recruits states that since most time is taken in positioning the recruits there is no time economy with miniature films. The claims for 35 mm films based on film cost is compared to 12 in \times 15 in (invariably based on small film purchases instead of by thousands) evade the fact that the film cost is only a fraction of the total establishment expenses. Magnification of 35 mm films cannot be increased to approaching normal size without the emulsion grain obscuring the detail of utmost importance in early lesions.

To popularize mass radiography articles have been published in the popular press (*Picture Post*, Feb 12, 1944), but nothing is stated that such examination cannot give immunity to later infection. Hence a false sense of security is given. At a Rotarian luncheon to which I was invited a lay lecturer gave me the impression that such examinations may be carried out by laymen only. Question strongly arises whether in practice secrecy can be maintained.

With the possibility of hostilities ending there is already a reaction against regimentation in normal life and in respect to tuberculosis, question arises whether propaganda should not be preferably directed towards the more early radiological examination of clinically suspicious cases with full size films at hospital or in private, at the instance and under the consideration of the patient's private medical attendant with resulting secrecy. The private medical attendant can best decide, on the basis of the report and his clinical observations, whether care and notification are necessary, or only an old lesion is being dealt with and secrecy can be maintained without danger to others. Once these cases become official, routine home inspections, loss of work time for periodical clinic attendances, etc., result, with publication of the patient's past condition and detriment to his present economic position. If one can judge by the difficulty of obtaining an impartial board which exists in respect to those enlisted in the Services and suffering from definite conditions, with many months before proper discharge, to remove the official classification of tuberculous will be equally difficult, particularly if the Ministry is to dictate the mode and technique of examination—I am, etc.,

BERNARD LEGGETT

London, E.7

Service Medicine

SIR—My reaction to Dr P. B. Corbett's letter (Sept 9 p 355) is a desire to point out that as a civilian medical practitioner he is only on the very fringe of Service medicine, and is not in a position to express a true opinion as to its merits or demerits. The number of beds in his sick quarters suggests that he is in charge of a very small station and is therefore acting in the place of a very junior M.O. He probably does not realize the large amount of paper work that even his small station causes his Wing S.M.O. It is well known that junior M.O.s and C.M.P.s are not delegated the "responsibility" of paper work and have more time to devote to the rare case, presenting a clinical aspect of any interest, during the short time that it may remain in the sick quarters. In this they are more fortunate than their slightly more senior and more numerous brethren.

It is only partly true that the "crux of the matter is that the medical orderlies must know and do their part." It is my experience in five years in the R.A.F. during the war and one year in the Volunteer Reserve, and two C.M.P. appoint-

ments before the war, that it is rare to find orderlies who have the conation or volition to be trusted with more than menial tasks, and that to leave even the routine paper work entirely in their hands is to invite a shower of abuse and a visit from the Group S.M.O. A good staff is admittedly very helpful, but the very best cannot absolve the M.O. from the tedious completion of forms and procedures that are his sole responsibility. For example to send an officer on sick-leave four forms must be completed in manuscript of which no fewer than fifteen copies must be personally checked and signed. The completion of board action on an airman or airwoman on F 496 with M.P.B. 204 is equally tedious but necessary for the proper compilation of R.A.F. records. This form eventually bears the signatures of six medical officers (surely they could be better employed). As a C.M.P. Dr Corbett would never come in contact with more than the initial phase of these procedures. Another aspect of Service medicine of which he is in all probability happily oblivious is that of stores. The Service medical officer in charge of a station is responsible for everything in his sick quarters, even to the electric light bulbs, as he may find to his own financial disadvantage if he is negligent. To be classified as careful in this matter entails no small amount of time and labour spent in holding frequent "checks."

I could continue with examples such as these certainly *ad nauseam* if not *ad infinitum*. I am not entirely destructive in my criticism and I heartily endorse Dr Corbett's suggestion to provide the G.P. with a secretary to enable him to "have more time to devote to the clinical aspect of medicine," which (here I beg to contradict) is *not* the case in Service medicine, as I hope I have already made clear. Let us be under no delusion lest the red tape of Service medicine should be adapted to fetter civilian practice to the detriment of the care of the public—I am, etc.,

"SERVICE DOCTOR"

Thumb-sucking

SIR,—One of the lessons experience has taught me is never to be "oracular" with regard to medical matters. I particularly used the words "no doubt in my mind" for this reason. I have no wish to claim more than the right to express my own honest, considered opinion regarding the harmfulness of persistent thumb sucking. That opinion is founded on the detailed clinical observation of 3 400 children examined in the speech research, and on the clinical impression of 20 years' practice among children of all ages, involving the inspection of some 8 000 mouths each year. Some of these children I have now been able to re-examine at intervals throughout their entire school life from the kindergarten to the sixth form.

I am deeply interested in Dr Colin Edwards's contrary clinical impression (Sept 16, p 387), and would be sincerely glad to know the scope of his own experience. But, Sir, what exactly is a "flesh mortifier"? Am I supposed to be one? I hope not. It sounds very disagreeable—I am, etc.,

Manchester

MARY D. SHERIDAN

The Services

Capt W. R. Dalziel, R.C.A.M.C., has been awarded the M.C. in recognition of gallant and distinguished services in Italy.

The Efficiency Decoration has been conferred upon the following officers of the Territorial Army: Lieut. Col. A. M. Campbell and D. P. Levack, Majors (Temp. Lieut.-Cols.) M. DeLacy, H. G. Garland, and W. E. Orchard, Majors J. C. C. Howe, R. G. Morrison, and L. D. Williams, Capt (Temp. Major) C. S. France.

Capt W. L. Wainwright, Home Guard, has been appointed M.B.E. (Military Division) in recognition of gallant conduct in carrying out hazardous work in a very brave manner.

CASUALTIES IN THE MEDICAL SERVICES

Capt ROBERT ALASTAIR BOYS KINLOCH, R.A.M.C., previously reported missing in Burma, is now known to have been killed in action. He was the second son of Dr R. Blair Kinloch of St. Albans and studied medicine at St. Thomas's Hospital, qualifying M.R.C.S., L.R.C.P. in 1941. He joined the R.A.M.C. as a temporary lieutenant in January, 1942.

Obituary

SIR HUMPHRY ROLLESTON, Bt., G.C.V.O., K.C.B.

Former President of the Royal College of Physicians

With the death of Sir Humphry Davy Rolleston on Sept. 24 there has passed from our midst a physician who helped to sustain the literary tradition of British medicine which began with Linacre. But those who came within the wide circle of his friendship mourn even more deeply one who attracted and retained to an unusual degree the affection and confidence of his fellows. From the record of the offices he held and the work he did, as clinician, teacher, writer, and man of affairs, almost every hour of every day must have been fully occupied, yet his courtly bearing and manner always conveyed the leisure and dignity of the old school.

All the best traditions of his profession, its courtesy, its learning, its uprightness and devotion to truth, met in him. He was a teacher who had much to impart, but he remained to the end a humble learner, with a zest for fresh knowledge concerning things new and old.

His family descended from a branch of the Rollestons of the village of that name in Staffordshire. Sir Humphry's grandfather, the Rev. George Rolleston, was a fine old man of the almost extinct parson-squire type, who until his death in 1868 held the family living and also looked after the small estate at Maltby in the West

Riding. His son, George Rolleston, M.D., F.R.S., qualified at the age of 21, served as a medical officer in the Crimean War, returned home to become physician to the Radcliffe Infirmary at Oxford and Lees Reader in Anatomy at Christ Church, and in 1859 was appointed Linacre Professor of Physiology. George Rolleston was a dominant and gifted man, one of the earliest, if not indeed the first, to relate biology to chemistry. He married Grace, the daughter of Dr. John Davy, whose deep attachment to his brother Humphry, the famous chemist, inventor of the safety lamp and discoverer of Michael Faraday, makes a pleasant chapter in biography. George and Grace Rolleston settled in New Inn Hall Street, Oxford, and had a large family. Their eldest son, named after his mother's uncle, was born on June 21, 1862.

Humphry was educated at Marlborough, a school for which he cherished a lifelong affection, shown in later life by his presidency of the Marlburian Club. From Marlborough he went to St. John's College, Cambridge, of which he became a Fellow, afterwards an Honorary Fellow. At Cambridge he made friendships with several men who were to become famous in his profession, notably Donald MacAlister, eight years his senior, then medical tutor at St. John's. Rolleston gained first-class honours in both parts of the Natural Sciences Tripos, and then went on to St. Bartholomew's Hospital. He qualified for practice with his Cambridge M.B. in 1888 and proceeded M.D. in 1892. After serving as house-physician and demonstrator of anatomy at Bart's, during which time he wrote jointly *A Manual of Practical Morbid Anatomy*, derived from his experience of the post-mortem room, he became attached to the visiting medical staff, first of the Metropolitan Hospital, and then of St. George's and the Victoria Hospital for Children. No opening in the succession at Bart's was then within sight. He filled teaching posts in pathology at St. George's and had been demonstrator of pathology, physiology, and anatomy at Cambridge. At Cambridge he came into association with Sir Clifford Allbutt, who had recently been appointed Regius Professor of Physic there. Allbutt had been a friend of Rolleston's father, and now between the older man and the younger there began a close friendship which lasted until

Allbutt's death thirty years later. In the preparation of his famous *System of Medicine* Allbutt was greatly assisted by Rolleston. The work first appeared, in eight volumes, in 1896-9, and a revised edition, in eleven volumes, with Rolleston's name associated with Allbutt's in the title, in 1906-11. In both editions of this work, which still holds its place among the chief encyclopaedic medical works in the English language, Rolleston wrote several of the articles, notably those on alcoholism, diseases of the oesophagus, the small intestine, the adrenal glands, the spleen, and the lymphatics.

Meanwhile, in 1898, Rolleston was appointed physician to St. George's and held the active post for twenty years. When he retired from the full staff in 1919 under the rules of the hospital he was appointed emeritus physician for his lifetime, with the privilege of using cases in the wards for clinical teaching. He was also made a vice-president of the hospital. In 1925, on the death of Sir Clifford Allbutt, he was appointed to succeed him as Regius Professor at Cambridge. There could have been no more fitting appointment to that famous chair, with its four hundred years' history, than the man upon whose shoulders the mantle of Allbutt had so obviously fallen. He acquitted himself in it, as in all his positions, with distinction, and retired, under the newly imposed age limit, at seventy. In the year of his retirement he published a biographical history of the Cambridge Medical School, having already written a full-length life of Allbutt.

For a period of eight years, beginning before his election to the Fellowship in 1894, he was an examiner for the Royal College of Physicians. He also examined in medicine at various times for the Universities of Glasgow, Oxford, Cambridge, London, Durham, Manchester, Bristol, and Sheffield. He served the Royal College as councillor and censor, and finally, in 1922, as President, a position he held until 1926. His annual presidential addresses to the College during that period have been published, each of them a careful and complete disquisition. During the same period he represented the College on the General Medical Council, and later, on his appointment to Cambridge, he continued a member of the Council as representative of that University until 1932. As far back as 1895 he was Goulstonian lecturer to the Royal College, discoursing on the suprarenal bodies, which at that time were attracting much attention, so that it was opportune to review the state of knowledge concerning them. In 1919 he delivered the Lumslean lectures, taking as his subject cerebrospinal fever. In 1933-4 he was Fitzpatrick lecturer, and dealt with the history of the endocrine glands. In 1936 he expanded these lectures into an extensive monograph with a historical review. His Lloyd Roberts lecture in 1933 was on the association of medicine and literature, a subject that always charmed him. He delivered the Harveian Oration in 1928 on cardiovascular diseases since Harvey's discovery.

Sir Humphry Rolleston's work as a writer, a historian, and, perhaps most of all, a bibliographer deserves a separate memoir. At its best his literary style, like his penmanship, was neat as an etching. His care for dates and reference might have seemed to some people to amount to pedantry; but it was a part of his scrupulous courtesy. To be accurate with regard to names, dates, facts in general is, after all, a compliment which the writer owes to those who read him and to those about whom he writes. In many contacts with Sir Humphry Rolleston the only time we have seen him ruffled was when it was suggested that a reference, the verification of which would have been tiresome, might be passed without checking. It was a matter for regret, and yet it was a reflection of his own modesty, that he should have written so little relatively on his own observations and thoughts and so much on the observations of others, which he had carefully collected and collated. He was an omnivorous reader, and he had a regular system of filing and annotation. In using it he sought accuracy and completeness. He was ready at any time to sacrifice an epigram of his own for a quotation from somebody else, but it was important that the quotation should have appended to it the source. Medical literature was to him a kind of scripture, and he delighted in the construction of a concordance. In his Harveian Oration on cardiovascular diseases just referred to some 300 authors are quoted. In his *Medical Aspects of Old Age*, published in 1932 (a revised and enlarged edition of his Cambridge Linacre

lecture) almost 400 names of persons are given. In a little six-page essay on Thomas Sydenham which he contributed to D'Arcy Power's *British Masters of Medicine* the names of a score of eminent people are given and after the name of each one of them there follow in brackets the year of birth and of death. The research, the labour, the patience he expended over writings which in bulk were not large would have been remarkable in a man who had nothing else to do but sit in a library. When one got used to it this quiet writing crammed with facts was very enjoyable, the more so for an occasional unexpected piece of irony or humour.

The first important work to appear under his own name was *Disease of the Liver, Gall-bladder, and Bile Ducts* published in Philadelphia in 1905, and in a second revised and enlarged edition, in London 1912, and in a third (with Dr J W McNee) in 1929. Other shorter works were his *Medical Aspects of Samuel Johnson* published in 1924, an essay *On Writing Theses for the M B and M D*, republished in 1925 after an early appearance in 1911—one of the best, as it is the shortest, of medico-literary first aid manuals, the memoir of Sir Clifford Allbutt, published in 1929, the Osler Memorial Oration in 1930, and *The Two Heberdens* in 1933. Several pages of the British Museum catalogue are filled with the titles of inaugural and other addresses and monographs from his never wearying pen. In 1936 he began a new enterprise in the editorship of the *British Encyclopaedia of Medical Practice* in twelve volumes, writing several of the sections himself, including some interesting observations on the progress of medicine from pre-Hippocratic days. Amid all this output he found time to edit the *Practitioner* from 1928 onwards with Mr Scott Stevenson, and from 1934 with Dr Alan Moncreiff as joint editor.

In the South African War Rolleston was attached to the medical staff of the Imperial Yeomanry Hospital, Pretoria. In the war of 1914-18 he was consulting surgeon to the Royal Navy, with the rank of surgeon rear admiral, and here his knowledge and wisdom, matched by his energy and tact, enabled him to render great service, which was recognized by the King in the conferment of the K C B in 1919. Later he was a member of the Medical Consultative Board for the Navy 1924-35, also of the Medical Administrative Committee of the Royal Air Force. He served on several Royal Commissions, Departmental Committees, and the like, including the Royal Commission on National Health Insurance. Noteworthy was his service, under Lord Macmillan, on the Royal Commission on Lunacy and Mental Disorder, the sittings of which were extremely protracted. He took part in Home Office inquiries into industrial diseases from the point of view of the Workmen's Compensation Act, and was a member of the Colonial Office Committee on Medical Services, and chairman of the Ministry of Health committees on vaccination and on medical records. He was one of the two assessors at the public inquiry into the Crofton typhoid epidemic of 1937. On one of the severest mornings of that winter the tribunal began its sitting without him, and as he had a journey of several miles to make and was then in his seventy-fifth year his absence on such a day caused no surprise. But after a quarter of an hour he arrived, having been delayed by a snowbound train.

Of his work for the British Medical Association and its *Journal* much could be written. Although never a member of its Council nor a partaker in its medico-political activities, he rendered much quiet unostentatious service along his own particular line. His wise counsel, his accessibility, his willingness to give freely of his time and thought to matters which were often very detailed laid the Association under a great debt on many occasions. He joined the Association in 1895, and in that year he was honorary secretary of the Section of Pathology and Bacteriology. He was vice-president of the same Section in 1904, and of the Section of Diseases of Children in 1910. In 1899 he was vice-president of the Section of Medicine, and president of it at the Cambridge Meeting in 1920, and again at the Centenary Meeting in London in 1932. During his tenure of office as Regius Professor at Cambridge he became president of the Cambridgeshire and Huntingdonshire Branch. In 1926 he was awarded the Association's Gold Medal for his distinguished services. The engrossed testimonial handed to him on that occasion, after mentioning the objects of the award—namely, to recognize the work of those who "have conspicuously raised the character of the medical profession"—went on to state:

"Every member of the Association feels that the object has never been better fulfilled than in awarding the medal to you who, during your career, have added very much to the lustre of names already illustrious." Humphry Rolleston was fittingly added to a list which included the names of Clifford Allbutt, Dawson Williams, and, of an earlier generation, William Farr.

In 1932 he was elected a Vice President of the Association, and in 1935, when the Annual Meeting was held over-seas and had an Austral in President, he served as Acting President in London. He was always ready to defend the good name of the Association. Once after the late Lord Riddell, in a characteristically pert speech had accused the B M A of being a trade union and the G M C of snobbery, Sir Humphry rose at once and very effectively defended both institutions. He did much faithful work on headquarters committees over a period of twenty years especially the committees concerned with the arrangements for the Annual Meetings, with the Library, and with the science work of the Association, including the bestowal of scholarships and grants. One of the special committees in whose work he took a large part was that which considered the causes and treatment of arthritis, and he had a principal hand in the drafting of its report. Another noteworthy piece of service was his eighteen years' chairmanship of the Committee of Management of the Medical Insurance Agency.

His presidencies make a formidable list. He was president of the Royal Society of Medicine in 1918-20, having already been president of some of its Sections, including the Clinical Section and the Section of the History of Medicine, president of the Medical Society of London in 1927, and of the Association of Physicians in 1925 and 1929. He was also president of the former Roentgen Society and again of its reincarnation in the British Institute of Radiology. For ten years he presided over the committee of the Papworth Village Settlement. The treatment of tuberculosis and the rehabilitation of its victims was one of his interests, and he was consulting physician to the King Edward VII Sanatorium, Midhurst and the Royal National Hospital, Ventnor. Other societies which claimed his active interest were the Eugenics Society and the Society for the Study of Inebriety. He was chairman of the Voluntary Aid Detachment Council over a period of fifteen years. Probably his presidency of the London Cornish Association was thrown in as a light relief, his interest in Cornwall deriving from Sir Humphry Davy.

In 1923 he was appointed Physician-in-Ordinary to King George V, and created a baronet in the following year. He was the senior member of the team of consultants and specialists whom Lord Dawson called in during the King's long and serious illness in 1928-9. For this he was created G C V O. In 1932 until the end of the reign he was Physician Extraordinary. The number of honorary doctorates and fellowships he held was surely a record. He was an honorary D C L of Durham, LL D of Edinburgh, Glasgow, Bristol, Birmingham, and the National University of Ireland, M D of Dublin, and D Sc of Oxford. He was Honorary Fellow of the Royal College of Surgeons of England, of the Royal Faculty of Physicians and Surgeons of Glasgow, and of the Royal College of Physicians in Ireland, also an Honorary Freeman of the Society of Apothecaries of London. In medical circles abroad his name was held in great esteem. He was an Officer of the Legion of Honour, a corresponding member of the Academy of Medicine in Paris, and an honorary M D of Paris and Bordeaux. The Academy of Medicine in Rome also made him a corresponding member, and Padua and Madrid conferred on him their honorary degree. He was an honorary member of the Association of American Physicians, an honorary Fellow of the New York Academy of Medicine, and an honorary graduate of the universities of Jefferson and Pennsylvania. In 1936 he took part at Washington in a celebration much after his own heart—that of the centenary of the library of the Surgeon General's Office, U S Army, and in his commemoration address he paid a worthy tribute to John Shaw Billings and his assistants and successors, all superlative bibliographers. He came home "consultant for life" to the U S Army medical library.

He married in 1894 Lisette Ella, daughter of Mr F M Ogilvy. Their elder son, Francis Lancelot, was killed in action in the first European war, and their second son, Ian Humphry, who was in the Crown Colonies Civil Service, was killed in endeavouring to quell a riot in Zanzibar in 1936. Not much

had been seen of Sir Humphry in London during the war; he spent his last years quietly with Lady Rolleston at Haslemere in Surrey. But that indefatigable pen went on. He was a faithful friend to two Editors of this *Journal* and for many years helped them with frequent reviews and unsigned articles. Often, on the passing of a noteworthy figure in medicine, we received from him a beautifully phrased "appreciation," a perfect piece of appraisal, saying not too much nor too little.

FRANK DOUGLAS MARSH, M.B., F.R.C.S.

We regret to announce the death on Sept. 17 at Edgbaston, Birmingham, of Major Frank Douglas Marsh, M.C., honorary aural surgeon and laryngologist to the Children's Hospital, Birmingham, honorary surgeon to the ear and throat department of Queen Elizabeth Hospital, and clinical lecturer on diseases of the ear and throat in the University of Birmingham.

He was born at Edgbaston on Nov. 26, 1888, elder son of the late Frank Marsh, F.R.C.S., the well-known Birmingham surgeon. From Shrewsbury School he went to Trinity College, Cambridge, and graduated B.A. with honours in the Natural Sciences Tripos of 1910. At St. Bartholomew's Hospital he won the Shuter Scholarship and qualified in 1914. He served on the Western Front as an officer in the R.A.M.C. Territorial Reserve from 1915 to 1919, reaching the rank of major and winning the Military Cross, and was for a time otologist at the Royal Victoria Hospital, Netley. On demobilization in 1919 he returned to Bart's as house-surgeon, and took the M.A., M.B., B.Ch. degrees at Cambridge and the F.R.C.S. diploma in 1920. He then set up in Birmingham as a specialist in otorhino-laryngology, and besides the appointments listed above he became consulting ear and throat surgeon to the Nuneaton General Hospital, the Guest Hospital, Dudley, and other neighbouring hospitals.

Frank Douglas Marsh joined the B.M.A. in 1922 and was a member of the Otological Section of the R.S.M. He published a number of papers on his subject in the *Journal of Laryngology and Otology* and elsewhere. His widow was formerly Dr. Edythe M. Bankier.

DENNIS EMBLETON, M.A., M.B.

We regret to announce that Dr. Dennis Embleton died suddenly on Sept. 17 at Ashridge E.M.S. Hospital, Berkhamsted, where he had been pathologist during the war. He was well known at B.M.A. House as a member of the Pathologists Group Committee from 1932 onwards, and as a member of the Central Medical War Committee and its predecessor the Central Emergency Committee since 1938; he was also a member of the Special Practice Committee for two periods, and of the Conference on Pathological Services which met in the year before the war. When the Association held its Annual Meeting at Plymouth in 1938 he held office as vice-president of the Section of Pathology, Bacteriology, and Immunology.

Dennis Embleton was born in Madeira in 1881 son of Dennis Cawood Embleton, M.D., and was educated at Tonbridge School, Christ's College, Cambridge, and University College Hospital, London; he qualified in 1906 and took the M.A. and M.B. degrees at Cambridge in 1911. From schooldays his heart was in the laboratory: At U.C.H. he was appointed assistant pathologist in 1907, assistant bacteriologist in 1910, and bacteriologist in 1919; he had been assistant lecturer on bacteriology in the medical school since 1912. He served during the last war with the rank of major, R.A.M.C., in charge of the laboratory of the Royal Victoria Hospital, Netley, and was also district cerebrospinal fever officer and district tetanus inspector. Embleton published a number of articles in medical and scientific journals, both in this country and on the Continent, on the dietetic treatment of diabetes, the pathogenicity and virulence of bacteria, the Wassermann reaction, the tuberculin reaction, bacterial endotoxins and exotoxins, meningococcus infections, and bacterial carriers. One of his early writings was a joint paper with his senior colleague, Dr. F. H. Teale, on anaphylaxis and its bacterial aspects read at the Annual Meeting of the B.M.A. at Brighton in 1913. Twenty-five years later he presented to the same Section an analysis of the glucose-tolerance curves from a large number of obese patients. He had been an active member of the

Association of Clinical Pathologists from the time of its formation.

A friend of undergraduate days writes: We have lost medical scientist who worked always in strict obedience to his sense of duty. Dennis Embleton was steadfast of purpose and honest to the core. Great height and almost boyish good look made him a conspicuous figure anywhere; and it needed little discernment to perceive the thoroughness and sincerity of the man or the natural reserve behind his straightforward speech and manner. In congenial company he would unbend, with most delightful smile and sense of fun.

HELEN LUKIS, M.D., B.S.

We regret to announce the death on Sept. 9, after a long illness of Dr. Helen Lukis, honorary medical officer to the Kingston Victoria Hospital, Surrey. For a number of years she has been a keen worker for the British Medical Association, both at headquarters and as secretary and, later, chairman of the Kingston-on-Thames Division.

Dulcie Helen Lukis was the youngest daughter of S. Pardey Lukis, K.C.S.I., who was Director-General of the I.M. from 1910 until his death in 1918, and held many other high offices in India. One of her brothers, T. S. Lukis, after brilliant career at his father's hospital (Bart's), was killed in action in 1915. Helen studied medicine at St. Mary's Hospital and graduated M.B., B.S.Lond. in 1923. She obtained the M.D. degree in 1926 after serving as house-physician and house surgeon at St. Mary's. Settling-in practice at New Malden she worked also as honorary anaesthetist to the South London Hospital for Women and Children and, for a time, as clinic assistant in the ear, nose, and throat department of the Queen's Hospital, Hackney. Her excellent essay, which won the Sir Charles Hastings Prize of the B.M.A. in 1934, was published in the following year as a book under the title *Problems of Anaesthesia in General Practice*. This dealt with every side of anaesthesia from the point of view of the practitioner, and it filled a gap in medical literature; the aim throughout was to show the reader how to do the best for his patient, coupled with a recognition that what is best in the hands of one type of administrator is not necessarily the best in the hands of another type. Her active service in the B.M.A. began thirteen years ago when she undertook the duties of honorary secretary of the Kingston Division, and on relinquishing that office in 1937 she was elected chairman. She represented her Division at eight consecutive Annual Meetings (1929-36); she served on the Journal Committee for two periods; and she had been a diligent member of the Organization Committee, the Propaganda Subcommittee, and the Maternity and Child Welfare Subcommittee.

All who knew Helen Lukis's energetic nature and gaiety of spirit will feel sorrow at the passing of a very able colleague at an age when many years of good work should have lain ahead of her.

A colleague writes:

Helen Lukis's choice of general practice in preference to specialization was an index of her outlook on the profession. To her the patient was a human personality and not merely a "case," and when the human as well as the clinical aspect of medicine appealed to her, the continuity of general practice gave something which lies outside the experience of a consultant. And because she had her heart in the human side of her profession and brought a personal interest, steady cheerfulness, and a calm competence to aid her undoubted ability, her eighteen years of service in Malden built up for her practice of considerable size among men, women, and children drawn from all circles of society over a wide radius—a practice which she was "our Doctor Helen." Apart from her main work as a general practitioner she had considerable local reputation as an anaesthetist and an expert on eyes. She served on the honorary staff of the Kingston Victoria Hospital for a number of years as surgeon. It was characteristic of her that, the busier her professional life became, the more she filled her fragments of leisure. An adept organizer, she applied that gift in double measure to her own life and managed to pack into a few spare hours activities which would have fully occupied a woman with no other ties. Social life meant, for her, active use of body and mind. She took a lively part in those local activities which marched with her profession. As divisional surgeon she did much for the prosperity and efficiency of the local branch of the St. John Ambulance Brigade. But, above all, she loved young people and was the beloved aunt, not only to her many real nephews and nieces, but also of numerous children

whom she had brought into the world. Her life had included many victories over a frail body, and in the early part of the war the overload of practice life, plus the labour of love in building up first-aid organization in Malden, led to a serious cardiac breakdown. Having overcome this, she returned to her work to meet the strain of the London blitz, the reduction in number of practitioners on civil duty, and the peak-load of Boards for the Women's Services. In the early part of 1944 the onset of her last illness came, and, after a gallant and ever-cheerful period of suffering, she entered into her rest.

News has reached this country from New Zealand of the death of a very old member of the British Medical Association, Dr. JAMES WHITTON, who was elected as long ago as January, 1892. He died suddenly on July 3, 1943, from an attack of angina pectoris at the age of 83. Dr. Whitton studied medicine in Dublin and graduated M.D. of the old Royal University of Ireland in 1880. He obtained the M.A.O. degree in 1886 and the F.R.C.S.Ed. diploma in 1899, having taken the licence of the Edinburgh College in 1883. After practising in Wellington, N.Z., for many years, he retired from active work and lived in the suburb of Lower Hutt. His wife survives him.

L. V. C. writes: Having known Dr. ALEXANDER FRANCIS professionally for over forty years and enjoyed intimate knowledge of him and his work I feel that, in justice to his memory, I cannot do less than place on record his unselfish devotion to the relief of suffering asthmatics. Combined with his special treatment, attested to in the admirable obituary notice published on Sept. 2, no possible factor was omitted from his survey of each case, and his patients were always loud in their praise of his thoroughness, and many almost worshipped him for the difference he had made to the comfort of their lives. He will be greatly missed.

EPIDEMIOLOGICAL NOTES

Discussion of Table

England and Wales notifications of dysentery, scarlet fever, measles, and diphtheria were higher than last week by 203, 14, 69, and 36 respectively. Those for whooping-cough fell by 166.

The only local increase of any size in the notifications of scarlet fever occurred in Lancashire, where 63 more cases were recorded than last week. In Durham there was a rise of 59 in the notifications of measles. The incidence of whooping-cough tended to fall in most areas, but the only decreases of note were in Lancashire and Gloucestershire, which had respectively 42 and 41 fewer cases than last week. Deaths of infants from diarrhoea and enteritis in the large towns rose from 63 to 102.

The record total for dysentery notified last week was exceeded by 203. The majority of the 622 cases occurred in the north. The chief centres of infection were Hertfordshire 80, London 6, Surrey 67, Southampton 45, Essex 38.

In Scotland there was again a small rise in the common infectious diseases of childhood; the increases over last week were: diphtheria 11, measles 19, scarlet fever 20, whooping-cough 69. The notifications of dysentery rose by 18, 55 of the total of 111 cases being in Glasgow. Deaths of infants from diarrhoea and enteritis fell from 57 to 31 in the large towns, all but 4 of these occurring in Glasgow.

In Eire the high incidence of diarrhoea and enteritis among infants was maintained; 136 of the 172 cases were reported Dublin C.B.

In Northern Ireland the notifications of diphtheria rose by 11, the largest return for this disease was Antrim R.D. 6.

Week Ending September 16

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,591, whooping-cough 083, diphtheria 541, measles 1,155, acute pneumonia 291, cerebrospinal fever 37, dysentery 351, paratyphoid 8, typhoid 5, fourteen cases of poliomyelitis were reported during the week, and 2 of poli-encephalitis.

Correction

It is regretted that several small errors occurred in the printing of the table of infectious diseases for the week ending Sept. 2 (Journal, Sept. 23). Notifications of measles for England and Wales were 1,069, instead of 1,669 as printed. Thirteen cases of paratyphoid fever were notified in England and Wales, 1 in London, and 3 (paratyphoid B) in Scotland. There were 10 cases of typhoid fever notified in England and Wales, 2 in London, 4 in Scotland, 14 in Eire, and 1 in Northern Ireland. No deaths were reported for either of these diseases.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Sept. 9.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county) (c) Scotland (d) Eire, (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London) (b) London (administrative county) (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available

Disease	1944					1943 (Corresponding Week)

Stillbirths Rate per 1,000 total births (including stillborn) ..	185	9	21	—	—	211	27	28	—	—

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Medical News

The opening address to students of the Welsh National School of Medicine, Cardiff, will be given by Prof W E Le Gros Clark, FRS, of the University of Oxford, on Tuesday, Oct 3, in the Medical School.

At the opening of the 103rd session of the College of the Pharmaceutical Society of Great Britain at 17, Bloomsbury Square, London, WC, on Wednesday, Oct 4, at 3 o'clock, the inaugural address will be given by the president, Mr Frederick George Wells.

The Food Education Society, 29, Gordon Square, WC1, announces that Miss Rose Simmonds, dietitian at Hammersmith Hospital, will give a lecture on "Food and the Sick," on Monday, Oct 23, at 2.30 p.m., at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street.

"Red Army Medical Service," will be the chief film at a special showing arranged by the Leeds Division of the BMA at the Majestic Cinema, Leeds, on Sunday, Oct 1, at 3 p.m. The programme will also include a film from the series on "Technique of Anaesthesia," dealing with nitrous-oxide-oxygen-ether anaesthesia. All medical members of the Services in the Leeds area will be welcomed.

The British Insulin Manufacturers announce that the prices of insulin, protamine-zinc-insulin, and globin insulin are to be reduced on Monday, Oct 2, when a new schedule of retail prices will come into operation.

On Tuesday, Oct 3, all voluntary hospitals serving the City and Metropolitan Police Districts will unite in their combined street collection. Gifts may be sent to the chairman of the Central Committee, Lord Luke, 36, Kingsway, London, WC2.

The Ophthalmological Society of Egypt (Dar El Hekma, 42, Kasr El Ainy Street, Cairo), in order to encourage scientific ophthalmic work, will award a prize to the value of £E 20 for the most valuable contribution brought before the annual congress of the Society by any of its members of less than 20 years' practice, according to regulations, of which a copy may be had from the honorary secretary.

Dr Alan Churton Taylor, medical officer in charge of first-aid post, Civil Defence Casualty Service, Southsea, has been appointed MBE, and Frederick George Mitchell, of the rescue service, Portsmouth, has been awarded the BEM. The citation in the *London Gazette* reads:

During an air raid a H.E. bomb destroyed premises, and a man was trapped in a cellar which had collapsed and was covered with wreckage from the building above. After debris had been cleared away, Dr Taylor and Mitchell entered the cellar through a small opening between two concrete slabs one of which was supporting the debris of the house. The casualty was trapped at the base of these slabs and the cutting of the reinforcement had to be effected by means of a hacksaw. Each time a piece of reinforcement was cut through the supporting concrete slabs moved thereby endangering the lives of the rescuers. Neither Dr Taylor nor Mitchell came out of the hole until the casualty was eventually removed 2 hours later. Dr Taylor and Mitchell showed courage and determination with a total disregard of personal danger.

A revised and enlarged British standard specification for conversion factors and tables (BS No 350 1944) has been issued by the British Standards Institution. This comprises linear, square, and cubic measures, measures of capacity, weights, speeds, stresses and pressures, weight per unit length, densities, concentrations, forces, moments, moments of inertia, work, heat, energy, and power. There are also temperature conversion charts and tables, and wire and sheet metal gauge sizes expressed in decimals of an inch and in millimetres. Copies of the specification can be had from the Publications Department, British Standards Institution, 28, Victoria Street, London, SW1, price 3s. 6d. post free.

The Czechoslovak Government, in consultation with UNRRA, has organized a medical mission which will shortly be leaving London to assist the health services of liberated Czechoslovak territory and to bring them sufficient hospital supplies to tide over the emergency period. The thirty doctors of this mission, led by Dr Ungar, many of them specialists in health administration, will be assisted by a staff of trained nurses and social workers. Their instructions are to follow as closely as possible upon the retreating enemy forces, surveying medical and nutritional needs and aiding in epidemiological control. The rapid organization of this mission has been made possible by the British Government and local authorities having granted immediate leave to Czechoslovak medical personnel.

Medical officers of health are asked to arrange for the medical examination, particularly with regard to tuberculosis, of nurses employed in residential and wartime nurseries in their areas. Any nurse found to be suffering from active tuberculosis in an infective state should be excluded from nursery work.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to The Editor, British Medical Journal, B.M.A. House, Tavistock Square, London, WC1. Telephone EUSTON 2111. Telegrams: *Articulate Westcent London*. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publisher, Manager, B.M.A. House, Tavistock Square, WC1, on receipt of proofs. Authors over seas should indicate on MSS. if reprints are required as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, WC1 (hours 9 a.m. to 5 p.m.). Telephone EUSTON 2111. Telegrams: *Articulate Westcent London*.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association, Telephone EUSTON 2111. Telegrams: *Mediseca Westcent London*.

B.M.A. SCOTTISH OFFICE: 7 Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Byssinosis Regulations

Q.—What are the Byssinosis Regulations? In my district no one seems to know them.

A.—Schemes for compensation and benefit for byssinosis have been made by the Secretary of State under the Workmen's Compensation and Benefit (Byssinosis) Act, 1940, and came into force on May 1, 1941. Administrative and Medical Boards appointed by the Secretary of State administer them. The compensation scheme applies to all male workmen employed at any time on or after that date for a period or periods amounting to not less than 20 years in cotton rooms, blowing-rooms, or card-rooms, in factories in which the spinning of raw cotton is carried on. The weekly payments made are the same as those made in respect of total incapacity under the Workmen's Compensation Act. The benefit scheme applies to all male workmen employed under the same conditions as above, before but not on or at any time after May 1, 1941. The benefit payable is 15s. per week. For both schemes the workman must be totally and permanently incapacitated for work, or, for the purposes of compensation only, have died as a result of the disease. Fuller details of both schemes are given in Statutory Rules and Orders, 1941, Nos 525 and 625, and 1944, No 504, published by H.M.S.O., and other particulars may be obtained from Mr John Lowe, the Secretary of the Administrative Board, 68, Deansgate Arcade, Manchester, 3.

Surgical Treatment of Migraine

Q.—A patient with very severe migraine for the last few years has tried various types of treatment without the slightest result. Is the operation of cutting the cervical branch of the sympathetic nerve any use?

A.—An account of the surgical treatment of migraine by section of the cervical sympathetic was given in an article in this *Journal* written by G. F. Rowbotham (1943, 1, 12). Very few cases have been done, but enthusiastic results have been reported. There is a certain amount of anatomical evidence to support an operation of this sort, but at present it is best to treat with reserve the results which have so far been published. The disability resulting from section of the sympathetic high up in the neck is not great, and this alone might justify the procedure as a last resource when all other methods have failed.

Tentorial Pressure Cone

Q.—Would you state briefly the causes of "traumatic tentorial pressure cone," and the chief diagnostic symptoms and signs?

A.—The prime cause of traumatic tentorial pressure cone is increase in pressure above the tentorium. After trauma this is likely to be a haematoma, either subdural, extradural, or intracerebral, or cerebral oedema or infection. It is unwise to look upon the condition as different from a pressure cone due to any other cause of high intracranial pressure. The main symptoms and signs are those of the cause. There will be signs of a head injury with high pressure and the patient will probably be in coma. Added to this there will be signs of the complication, such as intra- or extra-cerebral bleeding, and, finally, there will be the signs of the cone itself. These will usually be variations in consciousness, with altering pupillary signs, increasing external ophthalmoplegia, and also alterations in the pulse rate—in short, signs of brain-stem compression. Lumbar puncture may show a very low pressure or the physician may be unable to obtain any cerebrospinal fluid at all; but this must not be expected, for the interruption of the flow of cerebrospinal fluid is likely to vary from hour to hour. In no event should cerebrospinal fluid be removed. The object should be to reduce pressure above the tentorium.

Death from Drowning and under Anaesthesia

Q—In the resuscitation of the apparently drowned by artificial respiration recoveries have been recorded after as long as 6 to 8 hours. In anaesthetic accidents when the heart has ceased to beat, the life of brain cells is generally accepted to be a matter of seconds only. What is the explanation of this apparent discrepancy? Is there any record of cardiac massage being tried in the former? What in your opinion would be the usefulness of this procedure?

A—The apparently drowned patient starts off with the advantage that, when resuscitative measures are applied, his body tissues do not have to exert an overdose of anaesthetic agent before normal respiration can be resumed. In anaesthetic misadventures it is rare for recovery to be recorded no matter what measures are resorted to, after the heart has ceased beating for five minutes. If an animal were held with its head under water until the heart ceased beating for a similar length of time, it is improbable that any restorative measures would be effective. Long delayed recovery of the apparently drowned after prolonged artificial respiration is explained on the grounds that over ventilation from artificial respiration, enthusiastically administered, prevents the resumption of normal respiration. A vacuum is pulled out of the water. If he is dead he is dead, and no restorative measures will be effective. If there is still a spark of life, artificial respiration by ensuring an intake of oxygen should effect recovery. Artificial respiration, however, is often applied with unnecessary vigour and maintained by a series of willing helpers. This hyperventilation lowers the CO_2 in the alveolar air below normal, and this, in turn, results in a lowering of the tension of the blood CO_2 below the level necessary to initiate normal respiration. At a class demonstration it can be shown that active hyperventilation on the part of the volunteer 'tends towards unconsciousness' (Haldane and Priestley, 1934, p. 189). Gross hyperventilation from artificial respiration militates against recovery of consciousness in the unconscious patient. Less enthusiasm in the matter of artificial respiration allows CO_2 to build up and start normal respiration.

The Vertical Fluoroscope

Q—What are the present views on (a) the use of the vertical fluoroscope and (b) scope for use in the consulting room? (c) Is it of great use in the diagnosis of chest conditions? (d) What type of fluoroscope would you recommend for use in the consulting room? (e) Is there any risk in using the fluoroscope and what protection is necessary?

A—Screening and radio-raphy are complementary to each other and only rarely can either be omitted without risk of error. Radiology plays a vital part in the diagnosis and control of the treatment of intrathoracic disease, as it is indispensable to establish normality. Training and experience in radiological interpretation and clinical correlation is imperative, without this the use of apparatus will be a menace and may degrade what otherwise might have been sound clinical judgment. The practitioner would be well advised to consider that, should trouble arise, his work may be assessed on the presumption that he has specialist training and experience.

For ambulatory patients (consulting room practice) the vertical apparatus is preferable, but units combining facilities for examinations erect and horizontal are available. The erect examination alone, however, would cover the greater part of consulting room practice. The apparatus should provide for radiography at not less than 4 ft 6 in distance and with an exposure time of not more than 1/10 second for the biggest patient. Screening alone is not an adequate examination.

With regard to protection, reference should be made to the recommendations of the British X-ray and Radium Protection Committee, available free on application to the General Secretary, British Institute of Radiology, 32, Welbeck Street, London, W.1, also to the article, 'Effects of Radiation on Workers' (Brit J Radiol Jan., 1943 p. 3) and to the reply in the Journal of April 1, 1944 (p. 480), and also Sept. 23, 1944 (p. 423).

Therapeutic Dosage of Iron

Q—What is the present explanation of the fact that the treatment of microcytic anaemia requires 100 times as much iron per day as is the daily requirement of iron in food? (90 gr of ferri et ammonii cit. contain about 1,000 mg. of iron and the daily requirement in food is 10 mg.) The hypothesis of Prof. Buncie 50 years ago was that medicinal iron protected the food iron from being changed into non-absorbable sulphide.

A—The dose of a vitamin or similar food principle required to cure an established deficiency is usually of the order of ten times the maintenance dose. Accepting the figure of 10 mg. as the daily requirement of iron in the food, we obtain a therapeutic dose of 100 mg. Fe, or 500 mg. (gr. 7½) of iron and ammonium citrate a day. In practice it is found that something like two out of three women with hypochromic anaemia will recover with a dose as small

as this. It is because of the third who will not that it is the rule to give much larger doses of iron. The therapeutic dose of iron by injection is only 30 mg. Fe (gr. 2½ iron and ammonium citrate), which unfortunately approximates closely to the toxic dose by this route. When women who are resistant to treatment with iron by mouth are investigated, it is usually found that their serum iron does not rise as it should after a dose of iron, and presumably therefore the iron is not being absorbed.

The factors concerned in the absorption of iron are complex, but it is doubtful whether sulphide is of any importance. Medicinal iron is absorbed as such and used directly for the manufacture of haemoglobin, this has been demonstrated by giving preparations of iron which have been made artificially radio active by the cyclotron and can therefore be traced through the organism. The hydrochloric acid of the gastric juice is generally believed to promote the absorption of iron whereas phytic acid (from whole grain cereals) and phosphoric acid interfere. Reducing substances, such as are present in proteins, favour absorption of iron, and massive doses of vitamin C—i.e. 50 to 100 mg. t.d.s.—at the same time as the iron often have a striking effect. Absorption of iron is apparently favoured by a high concentration of bivalent ferrous iron in the lumen of the intestine and a low concentration of iron in the wall of the gut. The traffic is one way only—from intestinal lumen to epithelial cell, and from epithelial cell to plasma. We do not know the form in which the iron is transported, but for a time at least it may enter into complex combinations comparable with haemoglobin and cytochrome.

Coronary Thrombosis and Car Driving

Q—Is it safe for a man who has had one attack of coronary thrombosis to drive a motor car? I had an attack a few years ago and have acted on the assumption that it is unsafe. What precipitates an attack? Mine occurred in bed. My elder brother had one when walking up a long flight of stairs.

A—There is no reason why a man who has had an attack of coronary thrombosis and has made a good recovery should not drive a motor car. It might even be said that motoring would enable him to get about with the least exertion. It would be a different matter if there were cerebrovascular symptoms, but these are not expected.

Few conditions are known to precipitate an attack of coronary thrombosis. Occasionally loss of blood or an operation or a venous thrombosis may do so but in the great majority no immediate or extraneous cause for it will be found. The basic cause is an exacerbation of the atheromatous process, with thrombosis in the wall or lumen of the affected coronary artery.

Treatment of Ganglion

Q—Is there any other treatment apart from the 'Family Bible' and open radical removal for ganglion? Do they often disappear spontaneously?

A—Apart from surgical removal (itself not always radical on account of technical difficulties) there are other methods of treating ganglia which are occasionally used, although no sort of guarantee can be given that they will be successful. If the contents are reasonably fluid they may be aspirated through a large bore needle, aided by local pressure on the swelling, and a few minims of a sclerosing solution, preferably one containing carbolic, injected. This may require repetition. Another method is an adaptation of the seton. Stout threads, usually four, are inserted through the base of the ganglion by transfexion, the contents being expelled through the needle punctures by pressure. The threads are so tied together that the needle punctures are kept stretched open, they remain *in situ* for about ten days. Ganglia have been known to disappear spontaneously after violent use of the part (probably by rupture), but this is an infrequent event.

Treatment of Otitis Externa

Q—A male patient aged 65 of stout build with gouty tendency has complained for the past few years of intense irritation of the external auditory meatus with a sense of heat and fullness causing more recently slight deafness. He now has a chronic eczematous condition of the external auditory meatus. I have tried all the usual remedies but the condition recurs.

A—Dermatologists and otologists have twice combined to discuss otitis externa, which indicates its intractable nature. The degree of itching varies and requires treatment of the gouty tendency. Frequently the local eruption is maintained by remedies which are too strong and is at once relieved when simple applications are substituted, such as cleaning the meatus carefully with liquid paraffin and applying oily calamine. Small doses of x-rays may help. If debris accumulates the ear must be syringed out. Penicillin might help by attacking the infective fraction, but is not available for this purpose, on the other hand, sulphonamides almost invariably cause otitis. (See also answer given in the Journal of May 20, 1944, p. 707.)

Otosclerosis and Internal Secretion

Q.—What is the supposed connexion between otosclerosis and internal secretion? What kind of hormonal treatment of that disease is recommended?

A.—Some authorities have advanced the theory that otosclerosis may be caused by a lack of sex hormones, and have recorded apparent improvement in female otosclerotics following the administration of oestrogens. Most observers fail to confirm this. The cause of otosclerosis is still unknown, and so-called "cures" are usually due to suggestion. It is possible, however, that hormones, by their "tonic" effect, enable the patient to make a greater effort to hear. It is well known that the hearing power of such patients varies directly with the state of their general health.

Blue Bag for Stings

Q.—With reference to the recent question on bee stings and wasp stings (JOURNAL, Aug. 26, p. 295), there is, so far as I know, nothing that is so good as the old-fashioned washing blue, or blue bag. I should be most interested to know the composition of this. Perhaps it is efficacious on account of its alkalinity.

A.—There are a number of formulae for the preparations known as washing or laundry blue and blue bag. The essential constituent is ultramarine, which is compressed into a fairly hard mass with the use of binding agents to prevent its too rapid disintegration and solution. These binding agents are usually of an alkaline nature, such as bicarbonate of soda, and glucose is also commonly present.

The rationale for the use of blue bag for the treatment of wasp stings is not clear. Its use for bee stings is understandable, as these are acidic in nature. Wasp stings, on the other hand, are alkaline in nature, and it would appear that the use of a weak acid such as acetic acid or vinegar would be more effective. Nevertheless, blue bag is frequently used in the treatment of wasp stings and appears to give relief.

Habitual Hypnotic

Q.—I have recently seen two doctors who told me they take nembatal 3 gr. (two capsules) every night, which ensures them a good night's sleep and they wake up refreshed, as a result, in the morning. Otherwise they sleep badly. There is no question of taking more than 3 gr. nocte. Is any danger, other than habit, likely to accrue from this practice?

A.—Nembatal is one of the more quickly destroyed barbiturates and, therefore, relatively safe. The dose indicated would not be expected to produce cumulative effects. Idiosyncrasy to nembatal is exceedingly rare and would have shown itself already had it been present. The danger would seem to lie in the fact that such a habit postpones inquiry into the cause of the insomnia. The symptom is treated but the cause of it remains undiagnosed.

Diet for Steatorrhoea

Q.—A patient with steatorrhoea finds a fat-free diet monotonous. Are pancreatic extracts of any use?

A.—The fault in steatorrhoea is thought to lie in the intestinal cell, and as yet there is no specific therapy which can remove this fault. The causes of steatorrhoea are varied. Thus, it may occur in obstructive jaundice, gastro-colic fistula, extensive resection of the ileum for various causes, acute and chronic pancreatitis, some types of enteritis, after total gastrectomy, and, finally and most commonly, in the group comprising coeliac disease, adult idiopathic steatorrhoea, and tropical sprue. Recent work has shown that among the last group, at any rate, some have been due to pancreatic disease, but the diagnosis can be made only either by demonstrating an absence of pancreatic ferments by duodenal intubation or by necropsy. The amount of fat usually absorbed is about 95% of that ingested, whereas in steatorrhoea this figure falls usually to between 65 and 85%, except in severe exacerbations with diarrhoea. Under controlled conditions it has been shown that a high-protein diet leads to a higher percentage of fat absorption, and clinical experience has shown that the most consistently useful treatment is a high-protein diet with a restricted fat intake. Some relaxation may be made in many cases, especially in regard to butter, but the daily quantity of fat should not exceed 50 g. The need for increased protein in these cases has been recognized by the Ministry of Food, and extra meat rations can now be obtained in place of the normal fat ration.

Generally speaking, the use of pancreatic extracts and of pancreatic and duodenal secretions has been disappointing. The dried extracts show great variation in their potency and contents. In cases of proved pancreatic disease Rhoads and his co-workers have demonstrated some improvement in fat absorption by their use, and pancreatin B.P. gr. 15 twice daily two hours after food may be given a trial, but its use does not permit any marked relaxation in dietary restrictions. Many references will be found in a recent

article by Stannus (*Trans. roy. Soc. trop. Med. Hyg.*, 1942, 36, 123). A suitable 50-gramme fat diet is appended:

Daily Allowance.—1 to 1½ pints household skimmed milk. 3 to 4 oz. lean meat, liver, fish, rabbit, chicken, or lean ham. Restrict fats to 1½ oz. of butter or margarine. Note: *Obvious meat fat should not be taken.*

Breakfast.—Porridge, fruit, or cereal as desired. Tea with milk from allowance. Butter from allowance. Bread or toast without restriction. Jam, honey, syrup, or marmalade without restriction.

11 a.m.—Tea with milk from allowance, or meat extract or marmite. Toast or biscuits.

Dinner.—Meat from daily allowance. Potatoes and all other vegetables as desired. Vegetables must be well cooked, and boiled, not fried. Fresh, dried, or tinned fruit of all kinds. (Cooked fruit may be sieved if desired.) Milk pudding—e.g., sago, rice, tapioca, semolina, or custard—from daily allowance.

Tea.—Tea with milk from allowance. Bread as desired. Butter from allowance. Jam, honey, jelly, marmalade, or syrup as desired. Salad, tomatoes, etc., when available.

Supper.—Meat from daily allowance. Vegetables of all kinds without restriction (not fried). Bread without restriction. Butter from daily allowance. Fruit as desired.

The following must be avoided: Overdone and well-cooked meat. Food fried or cooked in fat. Dried and fat fish, such as salmon, herrings, trout, or mackerel. Grease, fat, salad dressing, sweet puddings, cakes, and pastry. Toffee and chocolate.

LETTERS, NOTES, ETC.

The Solvent of Colourless Flavine

Dr. J. B. KEARNEY (Kingston Hospital) writes: I would like to ask Mr. Victor Bonney and Mr. Sandeman Allen one question in connexion with their recent article on colourless flavine, in which they suggested that a solution of this substance might replace "Bonney's blue" as an efficient skin antiseptic (Aug. 12, p. 210). Is their rectified spirit really necessary? Our pharmacist informs me that it is much more expensive than ordinary industrial spirit. In Kingston Hospital "Bonney's blue" made up with industrial spirit suitably diluted has been used for many years as an external antiseptic with much success. However, it was chiefly in the treatment of vaginal discharges and septic skin conditions that it was used by us, and now, as we are contemplating utilizing this colourless flavine solution as a pre-operative skin antiseptic, we would like to know the views of the authors on the importance of rectified spirit in the make-up of their new preparation. Would not a suitable dilution of industrial spirit be equally or, at any rate, sufficiently effective as a solvent? If so, it would mean a substantial reduction in the cost of dispensing this antiseptic, and therefore would offer a greater likelihood of its becoming more universally popular.

Release of Wounded Medical Officer

M.B., CH.B. writes: I was interested in Dr. F. C. Durbin's observations on the Army Council's attitude to wounded medical officers (Aug. 12, p. 232). His remarks apply, not quite so forcibly, to those of us who have been invalided to Britain, after varying periods of service in overseas theatres of war, on account of chronic "medical" conditions. I am one of these unfortunates, now only fit for home service, and not likely to be fit for overseas service again. I have not applied for release, and I don't think many of us would do so, but there has never been any suggestion that I might be released, and my place taken by one of the many young men in E.M.S. hospitals and general practice who have not yet experienced the discomforts of Army life and separation from family and home, sometimes for many years. It would appear that the only way a medical officer can obtain release from the Services is either to be killed outright or be hopelessly mutilated, or to contract some disease which is considered to be incurable. There is no happy medium.

Interpretation of G.C.F.T.

Messrs. BURROUGHS WELLCOME write: In the reply which appeared under "Any Questions?" in the *Journal* of Sept. 2 (p. 327) it was stated that there was difficulty in obtaining a suitable antigen. We introduced "Wellcome" brand gonococcus antigen in May, 1942, since which time it has been used by a large number of workers and has been found completely satisfactory.

Disclaimer

Mr. E. HAMBLEY (Seer Green, Bucks) writes: I wish to dissociate myself entirely from the articles in the lay press which were written without my consent, and which were copied from my article in the *British Medical Journal* of Sept. 9 upon the subject of severe fracture-dislocation of the spine with recovery. May I also take the opportunity of apologizing for my omission in thanking Dr. K. Y. Mann in this article for his great assistance on the medical side in the case described.

BRITISH MEDICAL JOURNAL

LONDON SATURDAY OCTOBER 7 1944

SURGERY IN TUNISIA: NOVEMBER, 1942, TO MAY, 1943

BY

J. M. WEDDELL, C.B.E., F.R.C.S.

Colonel, late R.A.M.C. Late Consulting Surgeon, Allied Force Headquarters, British North African Force

It is proposed to give a short outline of the campaign in North Africa to describe the general lay-out of the medical units with the force, and to indicate some of the points of interest and lessons learned during that period.

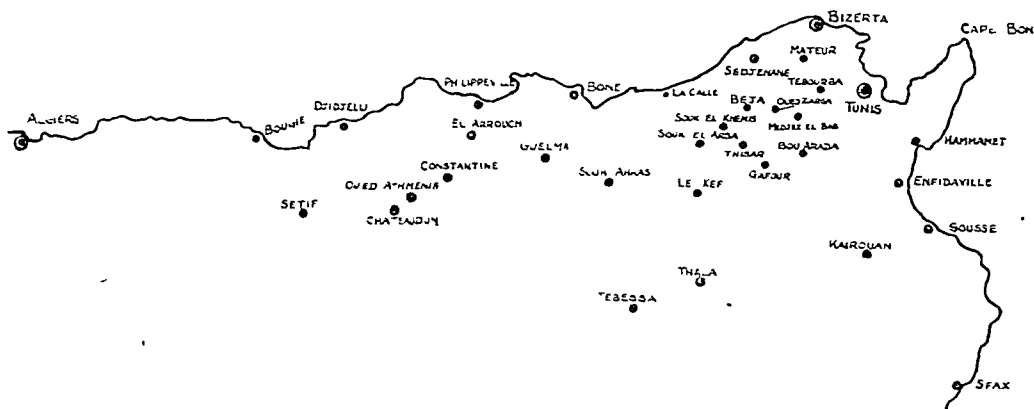

In Nov. 1942, American and British forces landed at various points on the coast of North Africa. The British force—called the First Army, but in reality at this time only two infantry brigades, a tank regiment, and auxiliary services—made landings on the coast of Algeria. The subsequent campaign may be divided into various phases: (1) the thrust forward of the First Army into the hills overlooking the plain of Tunis; (2) the build-up of the force; and (3) the final attacks on Bizerta and Tunis. During the first phase there was heavy fighting to establish our positions in the hills around Beja, Medjez el-Bab, and in the north round Sedjenane. The build-up occupied the winter months and early spring of 1943. During this period there was continuous hard fighting in the hills, which culminated in the capture of Longstop Hill and other key positions and made possible the final break-through to the plains of Bizerta and Tunis. Towards the end of this period the Americans had moved up from the south and taken over the northern sector of the line. The Eighth Army, in pursuit of Rommel, had broken through the enemy lines at Mareth and the Wadi Akarit and occupied Gabes and Sfax. The British and French forces held the central sector. The

and much improvement was necessary. A number of schools and barracks in Algeria were taken over for hospitals, and several of the general hospitals had to open up at once in tents. This involved a great deal of alteration and construction work for the Royal Engineers and Works Services. As time went on, a proportion of hutting was carried out for the tented hospitals.

The country was difficult. Much of it was mountainous, with narrow winding hill roads. Considerable stretches of plain intervened between the mountainous areas. The main roads were limited. There were two routes to the forward area—one inland through Setif, Constantine, and Souk Ahras to Beja and Medjez el-Bab leading on to Tunis, the other along the coast through Bougie, Philippeville, and Bone. A certain number of cross roads connected the two main routes.

The railway consisted of the main line through Setif and Constantine to Tunis. Branch lines ran from this to various places on the coast. The lines of communication were long and difficult; the distance from the main base at Algiers to the forward area was the best part of 500 miles by road.

In the winter months rain and mud made conditions extremely hard. The forward troops fighting in the hills, living in fox-holes and under any cover that could be found, had a gruelling time. The tented hospitals—until proper camp roads, concreted floors for operating theatres and tents, adequate

final phase included the capture of Bizerta by the Americans, the capture of Tunis by the First Army, the French, and some divisions of the Eighth Army, and the advance northwards of the main Eighth Army to the base of Cape Bon. The battle terminated with the round up and surrender of the whole of the enemy forces on the Cape Bon peninsula.

One difference between the Middle East and the North African campaigns was that the operations in the Middle East started from a large peacetime organization, whereas in North Africa everything had to be brought by a long sea route

sanitary annexes, and cooking arrangements could be prepared—worked under most difficult conditions.

By the middle of Jan. 1943, the medical lay-out was as follows. The main base was at Algiers, with secondary bases on the coast at Bougie, Philippeville, and Bone. At each base there was an Assistant Director of Medical Services at area headquarters. Other areas and medical units were on the inland route on the lines of communication. The Director of Medical Services for the force and his staff, including the consultants and advisers, were located at Algiers. Four general

hospitals were established a few miles outside the town in buildings (an orphanage, a school, and barracks) and partly in tents. One unit was in an excellent sanatorium at Rivet, in the hills about 20 miles inland, with good operating theatres, x-ray department, and wards.

At Bougie one general hospital was in tents about four miles inland from the port. Near Philippeville one 1,200-bedded general hospital was in tents at Ste Jeanne d'Arc, a small seaside resort about four miles east of the town. A 600-bedded hospital was in process of opening alongside. These were excellent sites on sandy ground sloping down to within a few hundred yards of the sea. Another 1,200-bedded hospital and a Canadian general hospital came later to El Arrouch, about 20 miles inland, both in tents. Near Bone one 600-bedded general hospital was in tents about 15 miles inland from the town. A 200-bedded general hospital was at La Calle, near the coast some miles east of Bone. Inland, the headquarters of the lines of communication were at Setif; the Deputy Director of Medical Services for the Lines of Communication was here, and a field hospital (50 beds) was in buildings in the town. Further east, on the Setif plateau, a 600-bedded hospital was at Oued Athmenia, partly in a good building and partly in tents. Later a 1,200-bedded general hospital opened at Châteaudun. A field hospital (50 beds) was at Constantine; at Guelma, a few miles off the main road, a 600-bedded hospital was open in tents. The most forward of the 600-bedded general hospitals was at Souk Ahras, near the Tunisian border: this was partly in buildings and partly in tents. For a time one 200-bedded general hospital was at Biskra. The personnel and equipment of this unit were moved to the site entirely by air.

In the forward area the C.C.S.s, F.S.U.s, F.T.U.s, advance depots of medical stores, and the field ambulances were with the First Army from Sedjenane in the north, through Medjez-el-Bab, Beja, and Thibar, down to Bou Arada and Gafour in the south. The Medical Headquarters for the Army, the D.D.M.S., and his staff were at this time in the neighbourhood of Souk Ahras. One parachute field ambulance dropped very early in the campaign near Beja and carried out 136 operations there in the first few weeks.

Evacuation from the forward area was by road, rail, and air. By road, evacuation was by motor ambulance convoy through the general hospitals to (1) Philippeville, Guelma, and Bone, and (2) Souk Ahras and Oued Athmenia, to Algiers. Rail evacuation, to begin with, was slow and difficult. Ambulance trains were improvised from ordinary French rolling-stock, but by degrees corridor ambulance trains became available. And by May, 1943, nine of these were working. In the early stages of the campaign evacuation by air from the forward area was not practicable, but was carried out, in considerable numbers, from airfields on the lines of communication. A large airfield was sited near Oued Athmenia, and the general hospital there evacuated many cases in quite early days.

When forward airfields were established round Souk El Arba and Souk El Khemis, and air superiority had been obtained, more forward air evacuation became possible. Certain difficulties were encountered: low cloud over the hills and poor visibility often made flying impossible. The arrival of planes on a forward airfield is apt to be capricious, and it is not always certain to what destination the planes will return. To take patients 20 miles or so over indifferent roads, make them wait several hours on the airfield, and then have to take them back is not good treatment. Also, to have a holding medical unit at a forward airfield is not always possible. Therefore air evacuation, though often extremely valuable, has its limitations.

By May, 1943, the total American and British cases moved by air in the British North African Force were 16,500. The average distance was 300 miles. The average time of each journey was two hours. The British cases numbered 4,400 (surgical, 2,400; medical, 2,000). All types of surgical cases were taken except the following: (i) perforating chest wounds in the early stages; (ii) pneumothorax; (iii) severe shock associated with heavy loss of blood; (iv) intestinal wounds or disease. Evacuation to the United Kingdom was based on a 90-day policy: that is to say, those who would not be fit for duty in 90 days were evacuated from the force. Hospital

ships and carriers sailed only to and from Algiers, so all cases for evacuation to England had to be collected that port.

Field Surgical Units

The F.S.U.s were the War Office scale of personnel, equipment, and transport. They differed from the Middle East surgical units in that, in North Africa, the F.S.U.s had more equipment, including 20 hospital beds and a lighting system. The personnel and transport were on a slightly more general scale. This was the first occasion these units had been mobilized for a field force. The Middle East had improved their own. At this time there were no field dressing stations (F.D.S.s), which were the units designed to combine with F.S.U.s to form an advanced operating centre. The F.S.U.s were therefore attached to C.C.S.s or the main dressing station of field ambulances as their parent units. I think that many of the difficulties met with in those early days are overcome by the F.S.U.s when they are combined with their complementary unit, the F.D.S.

As previously stated, the earlier months of the campaign were occupied in clearing the hills overlooking the Tunisian plain. During this period the C.C.S.s and F.S.U.s were comparatively static. When the general advance took place and the fighting became mobile these units were able to follow behind the fighting troops. Concerning this latter phase there are some points of interest:

On account of the short distances it was possible to group C.C.S.s and F.S.U.s at points fairly close to the fighting line. For example, at one time at Oued Zarga three C.C.S.s were grouped, each with two F.S.U.s and a field transfusion unit attached. These made an excellent operating centre 10 to 15 miles behind this portion of the front. Each C.C.S. admitted 100 casualties and then closed until 100 operations had been admitted by each of the other two. In this way surgical teams could work with a reasonable time for sleep, meals, cleaning up theatres, and after-treatment of patients.

Three 600-bedded hospitals and three 200-bedded general hospitals had been allotted to the D.D.M.S. of the First Army. These were made "movable" and were also grouped. In the battle of Tunis one group of these was located at Thibar, about 20 miles behind the C.C.S.s and F.S.U.s. They admitted third-priority cases from the front and staged cases operated on at the advanced operating centre. This was made possible by a system of sectional packing of the hospital equipment and by the excellent work of the Royal Engineers and Works Services in providing a piped water-supply, sanitary conveniences, concrete floors for operation tents, etc., all carried out within a very few days.

It was possible to spare an officer in charge of the surgical division of one of the newly arrived 1,200-bedded general hospitals, not yet open, to go round the C.C.S.s and F.S.U.s, work with them, and advise on operative technique and treatment generally. This was most useful, and is well worth arranging when possible, especially if some of the forward surgeons have not had much experience in dealing with battle casualties. Personal instruction and example are far more useful than all the paper one can send round. The officer in charge of the maxillo-facial unit had also been round advising the forward surgeon on the initial treatment of these cases.

An experienced operating ophthalmic surgeon was with the First Army. He had a lorry, a small technical staff, and optical equipment (lenses and frames), and toured the forward units and formations. In this way not only was skilled ophthalmic available as far forward as possible, but the replacement of lenses and spectacles was carried out in the most expeditious manner and a large amount of man-wastage saved. This was a forerunner of the mobile ophthalmic unit later created: the Consulting Ophthalmic Surgeon.

Team-work and Equipment

These units thoroughly justified their formation. They did excellent work throughout. The policy of bringing the surgeon to the wounded, within limits, is sound. Team-work is

* Grouping of C.C.S.s was first carried out in 1915 at El Siding, where Nos. 10 and 17 C.C.S.s were located and alternate periods of duty were taken. This grouping of two and often three C.C.S.s then became routine.

essential. The unit must work as a whole and each man have his definite duties. The orderlies have more to do after the operating is finished, and tend to tire sooner than the surgeon. All need reasonable time off, sleep, and regular meals.

The equipment on the whole was adequate. General demands for certain items were put to the War Office and have been supplied. Heating is necessary for the theatre and wards in cold weather. Two Valor stoves were authorized for each FSU in Tunisia.

A surgeon should not be kept with a forward unit too long. He must see at the base the results of forward surgery and thus complete his surgical education. I am of the opinion that a year is quite long enough for a surgeon to be with one of these forward units. If possible, a newcomer should work his way from a general hospital at a forward base where he can observe the later conditions of wounds and see the reasons for advising certain lines of treatment and the various troubles and difficulties which may arise during the evacuation of casualties.

Location of Advanced Operating Centres

These should be as far forward as possible. This undoubtedly does help the morale of the troops, but they must be in a position where the severe cases, especially wounds of the abdomen, can be retained in reasonable safety and comfort for at least ten days after operation. After treatment and good nursing are just as important as surgery. Early evacuation of these severe cases is disastrous. When it is possible to attach nursing sisters this is a great advantage.

Except in special circumstances, it is unwise to put a single surgical team forward with a field ambulance. One surgeon can cope with only a limited number of cases. The theatre staff do not finish when the operating is over, and they get more tired than even the surgeon. Also the nursing after-treatment and retention of the severe cases become more difficult.

[Note.—With reference to the location of advanced operating centres, it is of interest to recall an extract from a memorandum by the Consulting Surgeon to the Army after the last war:

"The conception of British surgeons is that no surgical operations of magnitude can be satisfactorily performed with a hope of a successful result if the patient has to be moved immediately after the operation. Consequently the arrangement is that, with a few exceptions, operation will be performed at the *casualty clearing stations*. These may be situated from 10 to 15 miles behind the actual fighting line, but experience has shown that, with modern motor ambulance transport, the extra time taken to get the wounded man a few miles further back than the main dressing stations of the field ambulance is only a fraction of the time spent in getting him from the place where he was wounded to the field ambulance. This extra time is well worth while to get the man to an area which will be more or less free from enemy fire, where more elaborate and permanent arrangements can be made for resuscitation operation and, more important still, where serious cases can be *retained for some days* at least and efficiently nursed before being evacuated further to the lines of communication or base.

The policy of having operating areas *nearer* to the fighting lines was tried in the British Army, and was definitely found to be *unsatisfactory*, even in the comparatively stable fighting line in France and Flanders.

"These advanced operating centres were primarily designed to deal with abdominal cases. In quiet times on the fighting front they did good work and undoubtedly saved lives owing to the proved fact that early death in cases of abdominal wounds is primarily due to haemorrhage. In periods of heavy fighting they failed. The reasons for this failure are that an operating unit situated close up to the fighting line could only rarely be efficiently housed. Accommodation for more than one or two operating teams was difficult and shelter for patients bad.

"The time taken to operate satisfactorily on one abdominal case is usually about one hour, and it is easily seen that if 40 or 50 abdominal cases arrived at such a centre a long period would elapse before the majority of cases would reach the operating table. The wounded would have a much better opportunity of receiving surgical attention if they were evacuated by motor ambulance transport another 10 miles further back, where they would take their turn with a mixed class of case. In addition, the difficulties of providing efficient nursing and after-care, on which British surgeons lay great stress, and the possibility of early evacuation on account of enemy fire and pressure of cases were

so much against the interests of the patient that this policy of operating arrangements close up to the fighting line is *not* now favoured."

On the clinical side it is proposed merely to refer shortly to points which were of interest so far as this force was concerned. Every opportunity was taken to make use of the experience gained by the surgeons in the Middle East, and their reports and surgical memoranda had been carefully studied. Copies of several of these had been sent to surgeons before the landings and from time to time fresh memoranda on surgery were issued.

First-aid Treatment

This was generally of a high standard. The Thomas splint, usually with the metal boot clip, was universally and correctly used. Tourniquets were rarely seen and rarely necessary. There was a tendency at times to overdo the injections of morphine. If patients passed through several posts they were sometimes found to have received as much as a grain of morphine by the time they arrived at the operating centre. Morphine is only very slowly absorbed in badly shocked patients. Men would also sometimes arrive with many cups of tea inside them.

Resuscitation

This was well provided for, and the field transfusion units did excellent work. The question of blood versus plasma has been much discussed. The experience of our surgeons was that cases with severe injuries could be restored to a reasonable condition with plasma, but that they would not then stand an operation of probably an hour's duration without blood. Blood will revive patients more quickly and enable them to stand the added trauma of operation much better than plasma alone. I consider that blood was neither wasted nor used excessively. It may be noted that with the advances made in resuscitation, more of the very severely wounded become fit for operation than was possible in the last war. Worse risks come to the surgeon and the actual post-operative mortality is probably higher, but certainly more lives are saved.

In attempting to forecast the numbers of patients who will require resuscitation various factors should be borne in mind. If the unit is dealing with first priority cases a large proportion, probably over 50%, will require resuscitation, if with second and third priorities, there will be many fewer. The longer the time lag in the receipt of the cases, the more will require resuscitation. Local conditions, cold wet weather, a long journey over rough roads, will also have their effect.

Anaesthesia in the FSUs and CCSs

Apart from the use of ether for laparotomies and multiple wounds, most patients were anaesthetized with pentothal. The advantages of this drug are the rapidity of induction and the freedom from post-anaesthetic vomiting—a point of the greatest importance in the busy post-operative wards. Pentothal with oxygen was very satisfactory for the thoracic cases. Many of the anaesthetics in the CCSs were given in a most competent manner by officers of the Army Dental Corps. The Oxford vaporizer proved a very satisfactory machine.

Types of Wounds

These varied greatly according to circumstances. Often the wounds were multiple. Mortars were much used, and were responsible for many of these. Mines caused many severe wounds of the feet and legs. It is essential to examine the whole of the patient, and extensive cleaning with soap and water and wide shaving should always be carried out.

Wound Treatment

Treatment was conducted on standard and accepted lines. In the early stages of the fighting one saw cases from which too much skin had been excised, a few attempts at primary suture, too tight packing of wounds, and insufficient division of deep fascia. This last was found especially necessary in wounds of the buttock, calf, and popliteal space. Attention was drawn to these points in surgical memoranda.

Extremities and Joints.—For transport during evacuation some form of the "Tobruk" plaster was universally used for the lower limb. Some surgeons developed slight modifications of their own.

The type generally used at this time was the encasing of the limb in plaster, with slits for the traction strapping and fixation of the limb to the Thomas splint with plaster bandages. The plasters were always padded and split. Details, with dates and simple diagrams, were, well marked on the plaster, and proved most useful. For the upper extremity the "U" plaster, from the nape of the neck and including the forearm, was mostly used, and proved satisfactory. The immobilization of extensive soft-tissue wounds had been advised, but was perhaps not carried out as often as it might have been. Traction for wounds of the knee-joint was occasionally found to have been omitted. The usual faults in plaster work appeared from time to time—carrying the plaster beyond the proximal crease of the palm, so that stiffness of the metacarpo-phalangeal joints and fingers results, lack of instruction to the patients to move the fingers and toes continually, faulty position of the ankle and foot. These faults always seem to be cropping up, and need constant attention. The results are very difficult to correct.

Abdomen—The treatment evolved in the Middle East was amply confirmed—suture, when possible, rather than resection; exteriorization and colostomy for wounds of the colon and rectum, gastric suction and intravenous therapy as a routine, and retention of cases for a minimum of ten days.

Chest—Conservative surgery (wound excision and closure of the open pneumothorax), with early aspiration, was the rule, and proved satisfactory. Great relief of dyspnoea was noted after the early aspiration of haemothorax fluid. Many breathless shocked patients were greatly relieved by being propped up, and these cases travel better in ambulances and trains when so positioned. The advantage of treating the shock by the completely recumbent position does not compensate for the serious respiratory embarrassment caused. In only a few cases was full thoracotomy indicated in the forward area.

Head—At the beginning there was some difference of opinion between the FSU surgeons and the neurosurgeons as to whether the general surgeons should deal with these cases. It was pointed out that in the forward units the general surgeon had no special equipment for this type of work. Diathermy was not available, x-ray examination was not always possible, and at the time there was only improvised suction. It was therefore accepted that it was better to get patients back to the neurosurgical unit with 48 hours if this was possible, for operation there. The sulphonamides—sulpha diazine when available—were always used.

Maxillo-facial Wounds—As little as possible was done in the FSUs and CCSs beyond cleaning up, the arrest of haemorrhage, and fixation of the jaw, when necessary, by the dental officer. These cases were then transferred to the maxillo-facial unit.

Burns—All coagulation treatment was forbidden as first aid. The routine was sulphanilamide and vaselined-gauze dressing. It was confirmed that cases of severe burns travel badly during the first five or six days after injury.

Sepic Sores—During the hot weather there was much man-wastage from sores on the exposed areas of the knee, elbow, and forearm regions. Often quite trivial in origin, they became chronic and resistant to treatment if neglected, and frequently meant weeks in hospital. There seemed to be no panacea for them. Unit medical officers were asked to get men with even minor skin abrasions, thorn-pricks, etc., to report sick at once so that they could obtain early treatment.

Whitlows—It was found necessary to issue an instruction that only the most minor conditions should be treated by unit medical officers. Much time and many bad results are saved by early admission to hospital. Too many midline and inadequate incisions under ethyl chloride were seen in the early stages of the campaign.

Chemotherapy—It was impressed on all that the sulphonamides are not a substitute for early surgery. These drugs were used prophylactically and therapeutically. To begin with, oral doses at four-hourly intervals had been advised for all wounded. In practice this broke down on the long lines of communication, and the Middle East sulphanilamide label, with the two doses at 8 a.m. and 6 p.m., was adopted. Owing to the universal use of these drugs, both orally and locally, it was impossible to evaluate their effect. The general impression was that they were of value in retarding the onset of infection. Also, as compared with the last war, the appearance and general condition of the men in the base hospitals seemed better. Although many wounds were infected the patients did not look so toxic and ill. Sulphanilamide, sulphathiazole, and sulphapyridine were the forms mainly in use for surgical cases. Some sulphadiazine was obtained latterly. Penicillin was not available in this campaign. The Penicillin Unit arrived in North Africa in May, 1943, and began investigations in one of the Algiers hospitals.

Anaerobic Infections—Tetanus Up to May, 1943, one case of generalized tetanus occurred in a German prisoner-of-war and one case of local tetanus in a British soldier. Both recovered. Gas gangrene. It is regretted that actual figures are not available. Up to May, 1943, there had been under 100 cases. Treatment was by early surgery, large doses of serum, and the sulphonamides.

Some Statistics

(a) The number of battle casualties operated on in 12 FSU and 6 CCSs between Nov., 1942, and May 15, 1943, was—total operations, 8,881; deaths, 331; mortality, 3.72%. It is interesting to compare these with some figures from the last war. On the Somme in July, 1916, 13 CCSs of the Fourth Army dealt with 14,400 casualties on the first day, 13,306 on the second day, and 8,793 on the third day. The surgical staff of the CCSs had, of course, been reinforced by a considerable number of surgical teams.

(b) Figures from four general hospitals in Algiers for the period Nov., 1942, to Sept., 1943 (wounds of the abdomen, chest, and head), were:

	Total	To Duty	To Conv Depot	Trans to Other Hosp	To U.K.	Died	Remaining	Mortality
Wounds of abdomen	287	77	54	14	129	8	5	2.7%
Wounds of chest	599	147	127	72	221	5	27	0.8%
Wounds of head	420	129	52	43	170	9	17	2.1%

Acknowledgments are gratefully made to the DMS of the British North African Force, Allied Force Headquarters, Major Gen Sir E. M. Cowell, and to the D.D.M.S., First Army, Brig E. W. Wade, for their courtesy and help. Also to Brig N. Canham, D.D.M.S., 5th Corps, for his unfailing interest in the surgical arrangements and the time he gave up to taking me round on all my visits to his area.

INVESTIGATION AND TREATMENT OF ENURESIS IN THE ARMY

PRELIMINARY REPORT ON 277 CASES*

BY

P. L. BACKUS, M.D., C.M.McGill, D.P.M.

T/Lieutenant-Colonel, R.A.M.C.

AND

G. S. MANSELL, M.R.C.S., L.R.C.P.

Captain, R.A.M.C.

As the result of considerable success in the out-patient treatment, since the outbreak of war, of nocturnal enuresis in soldiers by explanation, education, and suggestion, a fuller investigation of the problem has been undertaken in hospital. The findings and results of treatment presented below are based on the clinical examination and treatment of 277 unselected cases of nocturnal enuresis consecutively admitted to a military (psychiatric) hospital during the eight months ending Sept., 1943.

Examination

A full physical examination by the medical specialist was made at the time of admission. Special examinations were done on 232 cases as follows:

Bladder-function-test Cystometry—With due preparation and without local anaesthesia, a No. 8 E soft rubber catheter was passed into the bladder. The resistance to its passage was recorded by an arbitrary standard \pm indicated practically no resistance, +++, strong resistance. The bladder was emptied and boric acid solution at a temperature of approximately 100° F was allowed to flow into it at a pressure of 20 cm. of water. The base-line was taken as 1 cm. below the level of the pubic arch as the patient lay on the table. The apparatus used was a simple graduated glass container held on an adjustable stand. Fixed levels were maintained by moving the head of the stand up and down. A pressure of 20 cm. was chosen, as being just above that required to bring about an initial stimulus to micturate. This was confirmed by our preliminary test and is quoted by standard works on physiology. "18 cm." (Sampson Wright, 1940). At this level of pressure, flow was allowed to continue until the patient, having been previously warned, intimated desire to micturate, when the flow was immediately stopped. A volume reading was taken (see Table I). The patient was then encouraged to relax the bladder by increased control of the external sphincter muscles and an endeavour to create a negative pressure.

* A paper read at a meeting of Army psychiatrists held at York in July, 1943.

in the abdomen. This was reinforced by strong suggestion that the bladder was relaxing and getting bigger. When desire lessened or disappeared the flow of solution was allowed to proceed until a second stimulus occurred. A second arrest of flow was made and a volume reading was taken. This procedure was carried out a third time. These two latter readings are recorded as volumes under voluntary relaxation, and were taken at 20 cm. water-pressure in practically all cases. Two final volume readings called distension readings were then made under 40 cm. and 60 cm. water-pressure respectively. In a few cases pressure was raised to 70 and 80 cm. Volume readings above 600 c.cm. were taken in only a few instances. The ability to retain the solution under different pressures was noted, and was recorded on an arbitrary basis: — represented a leakage under 20 cm. pressure; \pm , a leakage under 60 cm. pressure; +, a leakage with catheter removed but controllable; ++, good control. At the end of the test the catheter was removed while the bladder was still full and the patient was asked to get off the table, walk across the room, and empty his bladder.

Psychological Examination.—On admission a preliminary psychological examination was made. Special attention was given to the history of the complaint. Periods of remission and relapse were investigated for psychological factors. A personality assessment was recorded at the end of the examination.

Findings

Anamnesis.—The youngest patient was 14 years of age; the oldest 45. Over 50% of the patients were of the ages of 18 or 23 inclusive. The average was 21.33 years. The intelligence score based on the matrix test ranged from S.G. I to V. The mean fell in the S.G. III+ group. The reference of cases or treatment undoubtedly showed selection. Length of service presented no important factor. Medical category was: "A," 10.15%; "B," 10.83%; "C," 9.02%. Bed-wetting at the time of admission was present in all but four cases. Frequency and urgency appeared in 82.67%, and precipitancy in 31.77%. Dysuria was complained of in only 4.4%.

There was a history of the main complaint—namely, nocturnal enuresis—since infancy in 75.81%. Of these, 82.81% had had no remission; though they had many free nights there was no sustained period of freedom. The remaining 17.19% had varying periods of freedom—several months and more. Approximately half of these cases relapsed during a non-service period. The other half relapsed during military service, and the relapse was attributed by the patient to Service conditions. Among the remainder—that is, 24.19% of the whole group—the complaint developed at varying periods in life; 18% occurred before and 42% after enlistment. In presenting these percentages no attempt is made to argue for psychosomatic relations; clinical findings only are recorded.

In the order of their importance the chief factors contributing to the persistence or onset of the symptoms were as follows. In the non-Service group: lack of any training; domestic difficulties in the home and feelings of insecurity related thereto; he so-called "broken home," such as separation of the parents; accidents and operations; sexual traumata or anxiety; the death of one or both parents; and air raids during childhood. In the group that appeared during Service life, failure to adapt to barrack-room life, regimentation, battle experience, accidents—especially injury to the external genitals—and operations were given as the cause of the complaint. 43.32% showed no gross emotional factor, but presented evidence of lack of proper care and training in their difficulties. Definite sexual factors were elicited in a remarkably small number of cases. Masturbation guilt was evident in only three. Of the 125 patients who were married only four gave a history of being affected by the marriage. Promiscuity and fear of venereal disease precipitated an attack in one and a relapse in another two. Punishment for the complaint was incurred in only 14% of the cases.

The school history of the group was a little above the average. The work history was quite the average for the personality type. A history of organic illness was reported in only a small number. There were no cases of overt abnormality of sexuality. Family histories presented very little of importance. A history of enuresis in parent or sibling was admitted in only 21% of cases.

Physical Examination

Physical examination by the medical specialist revealed no abnormality in 92.06% of cases. Of the remaining 7.94%,

genito-urinary disease was present as a chronic nephritis and as acute cystitis in one each and as a chronic prostatitis in one. There were four cases of stricture, apparently congenital, as emphasized by Winsbury-White (1941). Disease of the central nervous system presented one case of disseminated sclerosis. The remaining complaints were of an apparently unrelated type—namely, bronchitis, dyspepsia, and "rheumatism." Spina bifida occulta, as an incomplete development of the neural arches of the lower lumbar and sacral regions, was seen in only 13 out of 104 cases routinely x-rayed. In none of these was there any evidence of the symptom-complex known as myelodysplasia.

The Bladder-function Test.—The measure of resistance to the passing of a No. 8 E rubber catheter varied from practically no resistance (\pm) in 17 cases, + in 51 cases, ++ in 141 cases, to the very resistant (+++) in 9 cases. In addition actual obstruction to passage occurred in 14 cases; 10 of these were negotiated by an olive-tipped or coude gum-elastic catheter or a silver catheter. Four cases had to be sent to hospital for dilatation of a definite stricture. There was no serious complaint about the procedure. Only two refused examination.

Volume readings at the point at which the first stimulus to micturate occurred ranged from 30 c.cm. to 750 c.cm.—the former that of a very small bladder, the latter that of a case of early schizophrenia. Of the series 50% reacted to a volume stimulant between 100 and 250 c.cm. (see Table II).

Table I presents the volume readings of five different cases to illustrate individual findings. Case No. 98 had a small bladder with good initial relaxation. Case No. 79 had a small and very sensitive bladder. His frequency was always severe. Case No. 114 showed a fair average initial relaxation with good powers of voluntary relaxation. Case No. 46 had a bladder of average size but very sensitive. Case No. 163 had a large bladder with a large initial capacity and good powers of voluntary relaxation.

TABLE I.—Volume Readings of 5 Different Types of Case

Case No.	Type of Bladder	20 cm. Pressure			Distension	
		1st Stmn.	Voluntary Relaxation		40 cm.	60 cm.
			2nd Stmn.	3rd Stmn.		
98	Small	c.c.m. 160	c.c.m. 170	c.c.m. 180	c.c.m. 230	c.c.m. 270
79	"(sensitive)"	40	70	180	260	300
114	Average	250	320	370	450	540
46	"(sensitive)"	70	110	140	370	600
163	Large	370	460	560	650—	

TABLE II.—Volume Readings of the Series

Volume (c.cm.)	Stimul (20 cm.)			Distension	
	1st	Voluntary Relaxation		40 cm.	60 cm.
		2nd	3rd		
1—50	20	6	6	2	1
51—100	52	25	19	3	3
101—150	*51	34	23	7	3
151—200	36	*49	*37	12	5
201—250	32	36	33	25	15

801—				1	1
Mean: approx. —	143	198	239	400	500

* 50% — fall in between the heavy lines.

It will be observed that all patients showed some powers of voluntary relaxation after the initial stimulus. In sensitive bladders this was small, but under pressure the ultimate reading was much the same. Table II gives the volume readings of the entire series within 50 c.cm. Very few readings were taken beyond 600 c.cm. Only one reached 800 c.cm., and this was in an early experimental case. This volume was attained under voluntary relaxation with 34 cm. water-pressure. It is of

interest to note that this patient had previously been under hypnotic suggestion for bladder relaxation.

Waves in pressure-flow that were synchronous with respiration were often noted. However, in a number of other cases 39 were definitely recorded; more frequent waves appeared as the flow continued, and became more evident as the point of toleration was approached. It was felt that if apparatus of greater sensitivity were used further cases would have shown these rapid rhythmic waves. These waves are described by Denny-Brown and Robertson (1933), and are considered to be uninhibited bladder contractions, after the work of McLellan (1939).

The measure of sphincter control showed leakage under 20 cm. pressure in 1.29%, under 60 sm. pressure in 10% with the catheter, out but able to arrest the flow in 9.48%, and good control in 71.13%. Cystoscopy was done in 130 cases, and there was no report of any serious bladder disorder. It is not likely that abnormal cases would be referred to us for treatment. A pyelogram taken in 14 cases showed no important abnormality.

Psychiatric Examination

In the psychiatric study of the series it was found convenient to divide the cases into six main personality types according to the outstanding characteristics of each. As must be expected, there was a considerable admixture of two or more types. The largest group—namely, 48.01%—fell into what might be called a timid, immature, dependent, often frustrated type. Some of these showed definite schizoid trends. They came from the so-called "broken home" situations, or from homes where there had been much emotional stress in early life. On the whole, this group revealed marked evidence of "love deprivation" in childhood; a considerable number, however, showed strong "mother fixation." They nearly all gave a history of bed-wetting since infancy, and without remission. In other words, their bladders had wept for them in all their difficulties, while they themselves had refused or failed to grow up. If members in this group were allowed to go on leave while in hospital they reacted badly, and almost invariably relapsed when at home. The next largest group—namely, 27.07%—were of quite an average type of personality. They presented no important emotional stress in their history of childhood or later life. They, too, were largely chronic bed-wetters. It is of special interest to note that a great majority of these patients showed a considerable degree of real indifference to their trouble. Superficially they appeared anxious for treatment, but on deeper investigation the indifference became evident. They required much firmness in treatment to get them to make a serious attempt to help themselves. Having slept in wet diapers all their lives, they appeared to feel no great need for a change. The third group—10.49%—were those of a reaction type showing compensatory aggression. The fourth—6.14%—were what might be called pure aggressives; the fifth—5.77%—were essentially psychopathic personalities, and in some cases gave a psychotic family history. The remaining small group of 2.52% were predominantly obsessional in type.

Treatment

By the time the preliminary investigations were completed the patients had already been placed on suitable waking regimes. Fluids were prohibited after 6 p.m. The first move in active treatment was to get the patient to make as frank a statement as possible about his attitude towards his complaint. Following this, in terms easily understood by him, a careful explanation was given of bladder function and control. This was supplemented by a sketch on paper or by the simple device of interlocking the fingers of the two hands to represent the bladder wall. This was related to normal development and control in the average individual. It was conceded that a child might take three or four years to attain full control, and so it was understood that the patient might not achieve this in a night or two. That a prolonged lack of control had built up an attitude in which the patient had become hardened to his complaint was acknowledged; but, in view of his expressed wish to attain control and as he had an adult mind to bring to bear upon the problem, success was most definitely expected.

The aim was to achieve normal bladder control, and the consideration of this problem was based upon the known physiology of the bladder.

The aim and emphasis in treatment were all towards bladder control in its various aspects. Negative suggestion was scrupulously avoided. General fears of wetting the bed or finding oneself in a difficult situation were purposefully replaced by the positive expectation of holding the water under all circumstances. The bladder-function test formed a valuable practical basis for the discussion of the problem with the patient. A bladder of normal size with satisfactory sphincter control could not be denied. What was still more important was the knowledge that good powers of voluntary relaxation were present. When this could not be denied, emphasis upon a need for greater determination in certain aspects of control was self-evident.

The first exercise was therefore maintenance of sphincter control in the daytime. If the sphincter was weak, exercises in holding the water were carried out. The use of ephedrine as an adjuvant may be tried, but in our experience the results were disappointing. The second exercise was voluntary relaxation of the bladder—"Just as you did in the examination." With every initial urge to micturate, while the sphincter is held, the bladder is made to relax with the assistance of negative abdominal pressure by raising of the diaphragm and by strong auto-suggestion of bladder relaxation. This is best understood by trying it on oneself during a time of need. It was interesting to note how many chronic cases of frequency and urgency showed marked improvement under these exercises. Drugs such as atropine or belladonna may be used, and should be carried to full tolerance. These were also found of indifferent value. A dry mouth was a distinct handicap when the patient was restricted in water intake. Medical treatment has now been largely abandoned because of its doubtful value, which experience is supported by the findings of Browne and Ford-Smith (1941).

Nocturnal control was put on the same basis as day control, and was fortified by auto-suggestion at the time of going to sleep. Fears of accident were replaced by strong suggestion of positive control of the sphincter muscle. A "sleep tight" decision, so far as concerns that muscle, was the routine. The rest of the bladder, however, was expected to relax and to go to sleep just as the rest of the body did. This double suggestion of a tight sphincter and a relaxing bladder was given strong and repeated emphasis. It can with great benefit be made the basis of part of the group therapy for a ward. During subsequent psychiatric interviews this procedure was re-emphasized and the patients' determination stimulated. As soon as evidence of control appeared, the waking times were reduced in number and the procedure of "self-waking" was introduced if needed.

This new instruction was based on the idea that while the conscious mind was asleep the deep or unconscious part of the mind would remain in control. Emphasis was placed upon a determination that the latter would maintain continuous control over the sphincter, so that any attempt to force it open by a contraction of the bladder would result in its reflex closure of still greater intensity, such as occurs normally during the daytime. It was stressed that this increased contraction would persist up to a point of such acute discomfort in the bladder that it would wake the patient up. This, after all, is the normal function. One patient who captured the idea of the importance of this mechanism said that he was always waked by a feeling that a knife was being stuck into his bladder. He never wakened of his own volition before. The aim is so to focus the attention on an increase of bladder tone; so to sensitize the individual to it, that this normal mechanism will operate regularly and without failure. In adults this seems to be a much more useful procedure than the mechanical methods of waking, such as the use of the penile clamp of Baretz (1936) or attempts to condition the patient by use of an electric pad that when wet will ring a bell, as devised by the Mowbrers (1938). In these the stimulus comes too late.

As treatment proceeded one emphasized the successes and disregarded the failures. Analogies, such as learning to skate

POST-OPERATIVE CHEST COMPLICATIONS IN GASTRIC SURGERY

BY

T. W. MIMPRISS, M.S., F.R.C.S.

AND

F. G. ETHERIDGE, B.M., D.A.

(From Botleys Park War Hospital)

The purpose of this communication is to draw attention to the frequency of post-operative pulmonary complications in gastric surgery and also to assess the importance and severity of such complications. With this object, the post-operative chest condition of 100 consecutive patients on whom partial gastrectomy has been performed is reviewed. In submitting figures of the incidence of pulmonary complications for an operation such as partial gastrectomy it is necessary to give some information about the condition for which the patient was advised to undergo operation, together with the operative mortality. Also, the standards by which the pulmonary complications have been assessed must be stated.

Condition and Operative Mortality

It is generally recognized that the operation is more difficult if it is done for a peptic ulcer for which a previous operation has been performed, and more severe if it is done for an ulcer which is bleeding or for malignant disease. We have therefore classified our patients into four groups, stating the number of patients in each group, with the fatalities. (1) Those suffering from peptic ulceration on whom surgery had not previously been employed, apart from the suture of a perforation. In this group were 78 patients, one of whom died. (2) Those suffering from peptic ulceration on whom surgery had previously been attempted. There were 11 patients in this group, two of whom died. (3) Those suffering from peptic ulceration complicated by acute haemorrhage: 5 patients; one death. (4) Those suffering from carcinoma of the stomach: 6 patients; no fatalities.

It will be seen, therefore, that these operations were performed for the usual indications and were not confined to any special group of patients; and that of the 100 patients four died.

Assessment of Pulmonary Complications

Our practice has been to rely upon physical examination of the chest as a routine during the first two or three post-operative days. When any abnormal physical signs have been found, or a rise in temperature, pulse, or respiration rate suggests the possibility of a pulmonary complication, radiography has been carried out. In fact, 45 of our 100 patients have been x-rayed within the first few days of operation.

The primary types of immediate pulmonary complication encountered have been: (1) bronchitis, (2) lobar atelectasis, and (3) lobular or patchy atelectasis. We have diagnosed bronchitis in patients who after operation have had a productive cough with moist sounds in the lungs, but who on x-ray examination have shown no abnormality. The term "lobar atelectasis" is used when the whole of one or more lobes is atelectatic—a fact which can be well demonstrated on a radiograph.

The frequency of the diagnosis of lobular or patchy atelectasis, as Brock (1936) has pointed out, depends very much on whether or not the surgeon is looking out for this condition. In our experience it is by far the most common complication after operation. In most cases physical examination showed that the lower part of the chest on one or both sides was expanding somewhat less fully than normal, and auscultation revealed a poor air entry with some adventitious sounds. The temperature would be raised, often not more than to 100°, and the patient would feel that he wanted to cough but had some difficulty in doing so. He was encouraged to cough during the first or second day, bringing up some mucopurulent sputum. Following this the pulmonary condition rapidly improved and returned to normal. A radiograph of the chest in a patient of this type has shown slight elevation of the diaphragm together with slight patchy increase in density of the lung at one or both bases. In none of our cases in

this group was any mediastinal shift detected either by examination or by x rays. In a few patients this condition progressed to some more serious complication, such as broncho pneumonia; a fuller description of these patients is therefore given.

Incidence of Post-operative Pulmonary Complications

Working on the lines indicated above, we find that 34 of our 100 patients are classified as suffering from a post-operative pulmonary complication. Of these, 4 had bronchitis, 1 lobar atelectasis, and 29 lobular atelectasis.

Acute Bronchitis.—All these 4 patients were suffering from chronic bronchitis and had an exacerbation after the operation. In three the complication was not serious and did not prolong their stay in hospital; but in a man who had chronic fibroid phthisis of both apices together with chronic bronchitis the exacerbation of the bronchitis led to reactivation of tuberculosis and prolonged hospital treatment. In only one of these four patients, therefore, was the complication serious.

Lobar Atelectasis.—We recognized complete atelectasis of the lobe in only one patient. He was a man of 45 who had a collapsed right lower lobe which failed to re-expand rapidly. Twenty-eight days later a radiograph still showed that the lobe was not fully expanded. Bronchoscopy and aspiration of the secretion were carried out, and after this the lobe re-expanded. This complication prolonged his stay in hospital by some weeks, and must be considered a serious one.

Lobular or Patchy Atelectasis.—Of the 29 patients in this group, the right lower lobe was involved in 12, the left lower lobe in 10, and both lower lobes in 7. In 25 the complication was a mild one and for several days they suffered the discomfort associated with a post-operative cough; but the condition rapidly cleared, the lung re-expanded, and the cough and sputum ceased. In none of these cases was the stay in hospital prolonged owing to this complication, and it seems that the post-operative lobular atelectasis amounted to an uncomfortable nuisance rather than a dangerous complication. In the remaining four cases, however, this initial complication was attended by more serious sequelae, and was responsible for the death of a patient. These four cases are reviewed in detail:

Case 1.—A man of 69 who had a patchy atelectasis of the left lower lobe following an operation in the winter, when respiratory infections after influenza were frequent. He proceeded to bilateral septic bronchopneumonia and died on the eighth post-operative day. His death must be attributed to the pulmonary condition, as necropsy showed that there was no trouble below the diaphragm.

Case 2.—A man of 57 in whom operation was followed by patchy atelectasis of the left lower lobe. This subsided rather slowly and his cough had not entirely settled down on the tenth day, when an urgent operation for the removal of a gangrenous appendix with spreading peritonitis was carried out. He made a satisfactory recovery from this second operation, but his pulmonary condition was made much worse and consolidation of the left lower lobe followed. This proceeded to an empyema, for which surgical drainage was done. His stay in hospital was prolonged by many weeks, but he ultimately made a satisfactory recovery. He was unfortunate to suffer from an attack of appendicitis so soon after a major abdominal operation.

Case 3.—A man of 59, known to have a large chronic lesser curve and posterior-wall ulcer, was operated on as an emergency case on the fourth day of a severe haemorrhage. His condition was very bad in spite of repeated transfusions. Patchy atelectasis of the right lower lobe was present after operation, and he died on the eighth post-operative day from peritonitis and bilateral broncho pneumonia. Necropsy showed that the primary cause of death was a spread of peritonitis from the floor of the ulcer; the persistence and exacerbation of the pulmonary condition were almost certainly due to this peritonitis. His death therefore cannot really be attributed to a chest complication.

Case 4.—A man of 47 with a very high posterior-wall and lesser curve ulcer for which two previous attempts at cure had been carried out elsewhere. A very high partial gastrectomy was performed. The surrounding tissues were indurated, and it seemed impossible to obtain a satisfactory anastomosis between the cardia end of the stomach and the jejunum. A drain was therefore put down to the anastomosis and the floor of the ulcer. He developed a patchy atelectasis of the left lower lobe and also a left subphrenic infection, and died on the tenth post-operative day. Necropsy showed bilateral bronchopneumonia and subphrenic infection round

the anastomosis. It seems that in this case death was due to the inflammation round the anastomosis, which was probably responsible for the pulmonary complication.

It will be seen, therefore, that in only one of these four cases in which lobular atelectasis preceded bronchopneumonia was this sequel unconnected with a trouble in the peritoneal cavity.

To sum up: in the whole series of 100 patients there were 34 whose post-operative progress was complicated by a pulmonary abnormality. Of these, 28 suffered from a mild and transient complication, but six had severe pulmonary disease. Three died, but only one death was directly due to the chest complication. Of the three who recovered, the severity of the pulmonary condition was in one case due to peritonitis following an attack of appendicitis. It will be seen, therefore, that in this series of 100 patients, six developed a serious pulmonary complication—three being attributable to post-operative peritonitis and three occurring in patients whose condition was otherwise satisfactory.

Notes on the Series

The factors influencing post-operative pulmonary complications were excellently reviewed by Brock in 1936, and we will only comment on a few points which we have noted in our series.

1. The Operation

It is, of course, well known that upper abdominal operations are chiefly responsible for post-operative pulmonary complications in that diaphragmatic respiration is embarrassed. This embarrassment is likely to be accentuated by local peritonitis or post-operative distension of the stomach. Probably the most certain way to produce a post-operative pulmonary atelectasis is to do an operation which gives rise to a severe peritoneal inflammation. As we have just noted, necropsy showed that two of our patients had septic bronchopneumonia, and in our opinion this was secondary to peritoneal inflammation. We avoid any chance of post-operative distension of the stomach by the use of an indwelling Ryle's tube for at least the first post-operative day.

It has been suggested that a transverse abdominal incision allows the patient either to cough or to breathe deeply after the operation with less discomfort than is the case when a vertical incision has been employed. On 35 occasions we have made a transverse incision, and 12 of these patients suffered from post-operative pulmonary complication, while 23 remained clear. It does not seem, therefore, that a transverse incision, as employed by us, has any influence on the incidence of complications. What is much more important, in our opinion, is that whatever incision is made should be very well and strongly sutured: it is then easier for a patient to cough after operation. At the close of the operation the dressing is held on by elastoplast, applied so that it does not restrict respiratory movement.

2. The Anaesthetic

Our view is that the type of anaesthesia influences the severity of these complications rather than the incidence. A patient who develops lung complications after two and a half hours of third- or fourth-plane narcosis will be less able to combat them than a patient who has been in the second plane for a similar period.

In order to provide the requisite relaxation for gastric surgery and at the same time maintain the patient in the first or second plane, some sort of regional block is necessary. We use bilateral intercostal block of the sixth to the 'eleventh' nerves inclusive. The solution employed is 1/1,000 anethaine with adrenaline. No splanchnic block, in our opinion, is necessary with inhalation anaesthesia, and for some time now we have discarded it. Premedication is by omnopon-scopolamine, the average dose being omnopon gr. 1/3, scopolamine gr. 1/150. The narcosis is induced by pentothal and is maintained with cyclopropane, administered by a large-bore endotracheal tube and to-and-fro absorption. The second plane is quite deep enough for the whole of the operation, except for intubation and for traction of the stomach to free the upper end; the third plane is entered for these two procedures. This technique enables good ventilation to be maintained throughout, and since breathing is mainly intercostal in character this does not embarrass the surgeon.

Nosworthy (personal communication) has pointed out that the bronchial spasm following intubation in light anaesthesia should be avoided in patients in whom pulmonary complications are feared. It was our practice to give a decalin lozenge 20 minutes before operation and to intubate after a pentothal induction. This process gives rise to considerable reflex bronchospasm and can be avoided by deepening the anaesthesia to the third plane with cyclopropane and ether if necessary. Up to now the results of this method have been encouraging, but the cases have been too few for conclusions to be drawn.

Under the technique described above the patient is as fit as possible after the operation; fall in blood pressure and sweating do not occur. Aeration has been maintained throughout with a mixture containing a large percentage of inert gas (either air or helium). We are of the opinion that the agent employed for the narcosis is not of paramount importance; a few of these cases were done with ether, and the post-operative condition was satisfactory. We prefer cyclopropane because of its flexibility and the lack of toxicity when used in the lighter planes, but we have no hesitation in supplementing with ether should necessity arise.

3. The Post-operative Condition of the Patient

If the surgery and anaesthesia are of good quality the patient's post-operative condition should be good and he should be reasonably comfortable. This obviates the need for frequent injections of morphine and therefore avoids subsequent depression of respiration. We have tried to keep our patients both lively and comfortable after operation and to avoid the use of morphine as much as possible. It is, however, a fact that of five patients operated on for haematemesis only one developed a post-operative chest complication; yet these five patients received much more morphine, both before and after operation, than the average patient. We are now trying the effects of giving more of that drug after operation.

4. Effects of Sex

Of the 100 patients admitted for operation, 14 were females, four of them suffering from pulmonary complication. This shows no striking alteration in incidence compared with that in the male patients; but the figures, of course, are not large enough to enable one to draw any conclusion. As most of our patients have been on medical treatment for some time and their smoking has been reduced or stopped altogether, it is possible that this may explain why in our series the incidence has been about the same in both sexes.

5. Seasonal Incidence of Chest Complications

Of four patients with post-operative bronchitis, three were operated upon in the winter and one in the summer. Of 29 with post-operative lobular atelectasis, 16 had their operations in the winter and 13 in the summer. Of the 66 who had no pulmonary complication, 32 were operated upon in the winter and 34 in the summer.

It is, of course, well recognized that a patient suffering from chronic bronchitis is a better operative risk in the summer than in the winter. Apart from this, we do not think that in this country the incidence of complications is to any extent affected by the season; but the presence of an epidemic, such as influenza, seems to increase the severity of any pulmonary complication which may appear, and may lead to a troublesome infection in a partially atelectatic lobe. It is also very important, of course, to postpone operation should a patient show any evidence of respiratory infection.

6. Treatment of Pulmonary Complications

Prophylactic Treatment.—Satisfactory prophylactic treatment, of course, is what one wishes to obtain. We aim to keep the patient active and his lungs fully aerated during the post-operative period. With this end in view we give pre-operative breathing exercises to each patient so that he will know what is expected of him after the operation. We endeavour to keep his condition good by the performance of a sound operation under a well-administered anaesthetic and to have him in as fit a condition as possible shortly after the operation.

is completed. This enables one to avoid heavy or prolonged sedation. Post-operative breathing exercises are restarted the day after operation, and in most cases heavy percussion of the thorax is allowed to be carried out by the masseuse during the first post-operative day. Movements in bed are encouraged, and our patients are rolled for washing purposes during the first post-operative day, unless their condition is unusually poor. Clinical examination of the chest is carried out daily as a routine for the first few post-operative days, for both diagnostic and therapeutic purposes. We believe that the movement and the activity involved in the clinical examination of the chest have a useful therapeutic effect. Coughing is encouraged by all those who deal with the patient. We endeavour to avoid infection in a collapsed lobe by postponing operation in any patient who has an upper respiratory infection or is in any way unfit. We have also been giving 3 g. of sulphathiazole by mouth three hours before operation, followed by 1 g. four-hourly after its completion, for 24 hours. There is no evidence whatever that this measure is of any use, but it seems reasonable to suggest that it may lessen the risk of infection in a lobe which has some stagnant secretion in the air passages.

Curative Treatment.—Should a pulmonary complication be diagnosed, we rely on frequent breathing exercises and heavy percussion of the chest to assist coughing and expectoration of sputum. We try to keep the patient as active in bed as possible, as movement often forces an unwilling patient to cough. We have occasionally used suction through a tracheal catheter, both as a prophylactic at the end of operation and as a therapeutic measure, when there appears to be difficulty in coughing. It certainly seems to assist subsequent expectoration. Up to date we have not subjected patients on whom a partial gastrectomy has been performed to bronchoscopy within the first few post-operative days. We have, however, used this for patients who have undergone rather less severe operations, and are prepared to consider it in suitable cases in the future.

Discussion

One of the great difficulties in discussing post-operative pulmonary complications is to draw a line between what is a complication and what is not. Hypoventilation, as described by Beecher (1933) and others, is probably universal in patients after this operation. Henderson (1935) refers to "collapse without symptoms" as almost a normal sequel to major surgical operations.

In this series we x-rayed only those who showed some signs on physical examination. In a second series we are now x-raying every patient as a routine during the first or second post-operative day. It seems likely that in assessing his second series we shall find a rather higher percentage of mild patchy atelectasis, which was almost symptomless but was apparent on a radiograph if looked for. Probably few patients have a post-operative course entirely free from cough and sputum, and if one watches carefully enough some slight pulmonary abnormality can be detected. One's complication rate may therefore rise as time goes on, but this should be of little importance if the awareness of these slight abnormalities leads, as it should, to a reduction in the incidence of the more severe post-operative complications. In a second series we rather expect to show a greater incidence in the mildest type of patchy atelectasis.

We believe, however, that the avoidance of the more severe types of post-operative chest complication depends largely on the satisfactory post-operative condition of the peritoneal cavity. No amount of post-operative treatment will prevent those severe chest complications which are due to an unsatisfactory post-operative peritoneal condition.

Summary

The post-operative chest complications in 100 consecutive cases of partial gastrectomy have been reviewed.

A pulmonary complication was detected in 34 cases.

The influence of various factors is discussed.

TWO VARIETIES OF LEUKAEMIA IN ONE FAMILY

BY

R. W. MEIKLE, M.B., Ch.B.

House-physician, Western Infirmary, Glasgow

(From the Gardiner Institute of Medicine, University of Glasgow)

The aetiology of leukaemia is so obscure that all facts which might ultimately be of value in solving this problem seem worth recording. Leukaemia occurs sporadically, and familial incidence is rare (Whitby and Britton, 1942); hence the presentation of the following notes of the disease, which apparently involved different types of white blood cell, in a brother and sister of middle age. The two patients lived in the same house; there were no other members in the family, and there was no family history of other cases of leukaemia.

Case I

Mr. A., aged 46, was admitted to hospital on Jan. 20, 1942, complaining of a sore throat of six weeks' duration, with loss of weight and general weakness, slowly developing for a number of months. The chief clinical features were marked pallor, tonsillar enlargement with yellowish exudation but no obvious ulceration, cervical adenitis, and slight enlargement of the liver; the spleen was not palpable. Fever up to 100° F. was noted. The pulse rate was 120 to 140 a minute. Death occurred five days after admission, but a necropsy was unfortunately not permitted.

Case II

Miss A., aged 43, entered hospital on April 22, 1944, some two years after her brother, complaining of sore throat, spontaneous bruising over forearms and abdomen, a single epistaxis, and menorrhagia; there were also fatigue and headache of four months' duration. The chief clinical features were a sallow colour of the skin, ulceration of the throat with yellowish-white sloughs on the soft palate and tonsils, a single enlarged lymphatic gland at the right angle of the jaw, subcutaneous haemorrhages on the forearms and abdomen, and microscopic haematuria. Neither liver nor spleen was enlarged. There was fever up to 105° F., with rigors every evening. Pulse rate, 110 to 160 a minute. This patient died in coma six days after admission, and again no necropsy was possible.

Haematology

In Case I only a single blood count was done and a supply of films was taken for staining. The following figures were recorded: erythrocytes, 2,000,000 per c.mm.; haemoglobin, 55%; colour index, 1.4; leucocytes, 201,000 per c.mm. Differential count (1,200 cells): monocytes, 86.8%; monoblasts, 2.5%; lymphocytes, 7.4%; polymorphs, 1.7%; myelocytes, 1.6%. Nucleated red cells were also present, numbering 16 per 1,000 w.b.c.

It is to be noted in the differential count that there was a great preponderance (86.8%) of cells regarded as monocytes. These are contrasted later with the abnormal white cells found in the sister's blood. No sternal puncture was carried out.

In Case II two blood counts were done—on admission and again five days later. Sternal puncture was also performed. Blood examination (April 22, 1944): erythrocytes, 3,110,000 per c.mm.; haemoglobin, 51%; colour index, 0.8; leucocytes, 88,000 per c.mm. Differential count (1,000 cells): myeloblasts, 92.6%; lymphocytes, 6.6%; polymorphs, 0.8%. No promyelocytes or myelocytes were noted. On April 24 sternal puncture was performed; examination of the marrow confirmed the findings in the peripheral blood. Leucoblastic cells greatly exceeded erythroblasts in number, and again 92% of the marrow cells were regarded as typical myeloblasts.

Discussion

Apart from the interest of leukaemia of acute type occurring in middle age and affecting brother and sister living in the same house, the question whether both suffered from the same or from different haematological varieties of the disease requires discussion.

In the blood film of Case I 86.8% of the cells were undoubtedly typical monocytes, the majority of which, however, contained a convoluted nucleus, and were, in fact, identical with blood histiocytes as described by Levine (1934). One of these was seen to have ingested a red cell. The 2.5% of cells regarded as monoblasts contained large, round, densely staining nuclei, some of which showed one or two nucleoli; the cytoplasm, Leishman-stained, was blue and relatively small in amount. It is to be remarked that myelocytes and mature polymorphs together accounted for only 3.3% of the white cells.

Lymphocytes, mainly of the small variety, made up the remainder. A hyperchromic type of anaemia affected the red blood cells, the colour index being 1.4. Haematologically, therefore, the signs were those of monocytic leukaemia. Reference to the literature, however, indicated that these facts alone were not conclusive evidence in favour of such a diagnosis. The question arose whether the brother had died not of monocytic leukaemia but of a myelogenous leukaemia, which had been in the monocytic phase at the time of his arrival in hospital (Kracke and Garver, 1937). The absence of a marked myeloid reaction was regarded as a strong point in the support of the former diagnosis.

The striking feature of the blood picture in Case II was the presence of a high percentage (92.6) of mononuclear cells, each of which, when stained by Leishman's method, consisted of a round eccentrically placed nucleus, often containing nucleoli, and blue agranular cytoplasm, many were undergoing division. These cells were considered to be myeloblasts. Only 0.8% of the leucocytes were polymorphonuclear, and the remaining 95% were lymphocytes.

These findings, together with those in the bone marrow, clearly constituted a blood picture of myeloblastic leukaemia.

Conclusion

Two cases of very acute leukaemia, occurring in a brother and sister living in the same house, are reported. The sister's illness developed two years after her brother's death.

In the brother, a study of blood films strongly suggests the diagnosis of monocytic leukaemia, whereas the sister undoubtedly suffered from acute myeloblastic leukaemia.

I am very grateful to Prof J W McNee for helpful advice and criticism in the preparation of this paper and for permission to publish the second case. To Dr Forbes Walker, Ayr, I am indebted for the clinical details of the first case.

SUPERFICIAL GANGRENE IN ADOLESCENT DIABETES

BY

H. WHITTAKER, M.R.C.S., L.R.C.P.

Assistant Medical Officer, Leatherhead Emergency Hospital

Gangrene in the young diabetic is a rare event. Joslin (1940) the greatest authority on clinical diabetes, describes it as an accompaniment of arteriosclerosis, therefore developing almost entirely in the arteriosclerotic era of life. Of the few cases recorded in young people, some are determined by rare vascular accidents, disease of the blood vessels, or overwhelming infection of devitalized tissue. Kiefer, Brigham, and Wheeler (1926) reported frank gangrene of the entire left foot due to infarction in a youth aged 19 who was in diabetic coma complicated by pneumonia. Gangrene of the nose in three children under 10 years of age was described by Bowers (1924). Carbuncle, essentially a gangrenous lesion, may be a grave complication of diabetes at any age.

Recently we have seen two cases with a pathology obviously differing from the above rarities and from the common gangrene of the extremities of elderly diabetics. With their description is included that of a third case almost meriting the bizarre title *dermatitis artefacta gangrenosa diabetica*.

Case I

A boy aged 15 who had suffered from diabetes for three years was admitted to hospital on April 25, 1944, in coma. At an outpatient clinic on April 18 his diabetes had seemed to be well controlled by two doses of soluble insulin, with a noon blood sugar of 143 mg per 100 c.c.m., slight glycosuria, and no ketosis. Three days later an illness labelled "gastroitis" had started with much vomiting. Insulin, at first reduced, had later been omitted, and coma had inevitably ensued.

No complication was found on clinical examination. The coma was profound, with air hunger, ketosis, and extreme dehydration.

The pulse rate was 140, the temperature 98.2°, and the respiration rate 30. The blood pressure, at first 90/60, later fell to 80/50. A specimen of urine could not be obtained for some hours, but then showed gross amounts of sugar and ketones, with a strong reaction to ferric chloride. The blood sugar attained the notably high level of 1,320 mg per 100 c.c.m. Despite his coma the boy was so intensely restless that the insertion of a cannula into the right internal saphenous vein with splinting of both legs offered the only chance of maintaining the necessary intravenous therapy over a long period. This seemed a better arrangement than splinting of the arms.

Although four hourly attention to the back was scrupulously observed, a large area of gangrene, involving the upper part of the right buttock, suddenly appeared on the second day of splinting. The surrounding skin was red and indurated, and over the blackened skin of the gangrenous part small vesicles containing serous fluid arose. Separation at the edges was apparent by the third day, but a week later secondary infection had spread to the underlying fatty tissues and an abscess in the right buttock was evacuated. Culture of the pus produced *B. coli*. Consciousness was regained on the third day, and a complete recovery made from the coma. Fig 1 shows the gangrene as it appeared on May 15.

FIG 1—Case I. Photograph of the gangrene on May 15, one day before separation of the slough and eighteen days from the onset.

Case II

A soldier aged 24 was transferred on June 2, 1942, from another hospital for stabilization after diabetic coma. He had nounced thirst and polyuria for six months, but had felt quite well until a carbuncle appeared on the back of his neck on May 20. At this time he was on manoeuvres, and diabetes was not diagnosed until his admission to hospital on May 30 in diabetic coma, which lasted for two days. The blood sugar was then 560 mg per 100 c.c.m., and dehydration, ketosis, and peripheral circulatory failure seem to have been pronounced. The coma had been treated in the usual way and the diabetes was well controlled.

Each knee showed an area of dry superficial gangrene on the anterior surface. Overlying the surface of the flexed knee each area was 4 in long by 3 in broad on the right and 2 1/2 in on the left, the outer border on the right being just lateral and on the left just internal to the midline of the knee. The shape and symmetry of these lesions, almost mirror images as they were, suggested that they were due to pressure of the bed-clothes with the knees flexed and the thighs in a position of slight abduction and external rotation. There was no effusion into the joints or adenitis. Separation was complete in four weeks, and in six weeks the areas were healed.

The patient was well on discharge after four months, but in the interval many embolic abscesses, including a deep staphylococcal abscess in the adductor muscles of the left upper thigh, required surgery.

Case III

A packing-case maker, aged 29, who had been diabetic for three years, was admitted on July 15, 1942. Mentally a little dull, he was a most unstable diabetic, and the bruise on his left thumb, well shown in the photograph (Fig 2), attested to those insulin reactions, accompanied by diplopia, through which his erring hammer would miss the nail, held in his hand, and strike his thumb.

For the first of these three years of diabetes he had had great difficulty with his injections and had been warned not to inject too deeply. When asked to demonstrate his usual technique he produced to our horror, by the injection of 20 units of soluble insulin 40 units per c.c.m. in strength, an intradermal wheal corresponding in size to the lesions shown in the photograph. These consisted

of small round patches of dry superficial gangrene in all stages from discoloration to separation of the slough and fibrosis of the underlying granulations.

Attempts to reproduce the lesions both in this man and in normal controls were unsuccessful. During this time his diabetes was well controlled. No more gangrene has appeared since his use of the correct method of injection, but his diabetes is very unstable,

FIG. 2.—Case III. "Dermatitis artefacta gangrenosa diabetica" of areas used for insulin injections; July 9, 1942.

hypoglycaemic symptoms being frequent despite noon blood sugars of the order of 400 mg. per 100 c.cm. on some of his visits to the clinic.

Discussion

From the first two of these cases it would appear that even in adolescents a comparatively slight degree of pressure during severe diabetic coma will produce a local ischaemia which proceeds to gangrene. Of the various pathological factors present—ketosis, hyperglycaemia, dehydration, and severe peripheral circulatory failure—the last may well be the most important. That arterial disease plays no part is well shown by the intense local inflammatory reaction and the rapid localization and separation of the slough. Indeed, the contrast between the tedious dry gangrene of the extremities in the elderly diabetic and the condition just described is striking.

This condition receives small mention in the literature. In Brier's (1934) description of a case of gangrene of the face and ear in an untreated diabetic farmer aged 24, he notes that superficial gangrene of the heels also appeared. At so young an age as 18 days a female infant, whose case is described by Lawrence and McCance (1931), developed typical gangrenous lesions of pressure-points associated with a severe but temporary diabetes. Similar lesions of pressure-points in a woman aged 40 who was in typical diabetic coma have been named "dermatitis gangrenosa" by Riven (1935).

In the third case intermittent trauma by the intradermal injection of insulin over a period of two years in a badly controlled diabetic produced small areas of dry gangrene at the site of some injections. Lawrence (1944) gives a warning of the effect of intradermal injections, but such a case must indeed be rare, and is worthy of record as a curiosity.

I wish to express my gratitude to Dr. A. C. D. Firth for his kindness and help in this study of his patients, to Sir Francis Fraser for permission to record their description, and to Dr. R. D. Lawrence for helpful criticism.

Medical Memoranda

A Case of Petrositis

The following case is instructive, for it shows, that the serious condition of suppurative petrositis, complicated by extradural abscess, may be treated by a conservative operation preserving the hearing.

CASE HISTORY

On March 1, 1944, a girl aged 9 was admitted to hospital with acute left-sided otitis media and mastoiditis. She had a past history of several attacks of bilateral otitis media successfully treated with sulphonamides. Myringotomy was performed on the same day as profuse discharge followed. Sulphonamide therapy was begun in full doses. On March 5 she complained of severe persistent left frontal and post-orbital headache, and on the following day left external rectus palsy developed. Lumbar puncture revealed C.S.F. with a lymphocyte count of 9 per cmm, but otherwise normal. A diagnosis of mastoiditis and acute suppurative petrositis was made. A left cortical mastoidectomy was done on March 10 and a gallery of infected cells in the sino-petrosal angle was opened.

Although the general condition improved for a few days after the operation, the pulse rate remained high and the temperature did not settle. On March 15 she complained of: (1) severe left frontal headache, mainly in the distribution of the ophthalmic branch of the 5th nerve; (2) weakness when chewing on the left side (mandibular branch of 5th nerve); (3) deafness and giddiness. The deafness apparent a few days before now increased (8th nerve). The squint persisted (6th nerve), and there was some slight evidence of facial palsy (7th nerve). It was obvious that a lesion was present involving the courses of the 5th and 6th nerves. A small extradural abscess at the apex of the petrous temporal was diagnosed. Involvement of the 7th and 8th nerves was accounted for by diagnosis of acute petrositis and serous labyrinthitis.

Radiograph of Case.—A: Normal mastoid cells. B: Mastoid cells removed up to bony labyrinth. C: Track of abscessed bone. D: Site of abscess.

Operation (Mr. Magauran).—To preserve the hearing it was decided to approach the abscess along the superior surface of the petrous bone. This was done after removing the bone down to the bony labyrinth (lateral and posterior canals) and elevating the dura from this aspect of the bone. An extradural abscess containing a few cubic centimetres of pus was found after separating the dura for about 1½ in. Two thin rubber strips were used to drain the abscess, and 30% sulphacetamide injected into the cavity. The strips were removed three days later. The patient is now (April 15) well recovered. The wound is closing satisfactorily and hearing is nearly normal (whispering voice, 10 ft.).

Morbid Anatomy.—It was demonstrated at operation that the superior galleries of the petrosal cells were infected. Radiographs

ken after operation (see Fig) showed the amount of bone removed and the track of absorption of cells near the superior aspects of the one leading to the site of the abscess.

My thanks are due to Dr W C D Maile, medical superintendent, for allowing me to publish this case, to Mr W H B Magauran F.R.C.S., for an invaluable assistance in preparing this paper, and to the staff for their help and encouragement.

D. L. BRIDGEWATER, M B, B Ch,
Resident Medical Officer

Woking Victoria Hospital

Use of Dried Rabbit Plasma for the Staphylococcus Coagulase Test

In laboratories where occasional staphylococcus coagulase tests are done, supplies of fresh human or rabbit plasma known to be suitable for the test are not usually available. Fairbrother (1940) found that different batches of human plasma showed some variation in coagulability, and advised the use of positive and negative controls. Christie and Keogh (1940) observed that false positives occurred if plasma more than forty-eight hours old was used. We have found human plasma from transfusion blood unreliable. Rabbit plasma was therefore dried from the frozen state and tested for its suitability after prolonged storage at room temperature. This dried product has also been used in routine work for the past twelve months and found to be reliable and convenient for both the slide test and the orthodox tube method.

EXPERIMENTAL WORK

Selection of Strains.—From our collection of dried cultures of staphylococcus aureus six strains—two coagulase-negative, two weakly coagulase positive, and two strongly positive—were selected and used for testing plasma. It was of interest to observe that of no subcultures of a particular strain the culture which had been assayed through mice before drying had a coagulation time of ten minutes whereas the relatively avirulent strain maintained solely in artificial media for some time before drying had a coagulation time of five hours.

Collection and Drying of Rabbit Plasma.—Blood was obtained from rabbits by cardiac puncture; 10 ml of blood was withdrawn into a 20-ml syringe containing 10 ml of 4% sodium citrate in distilled water. The mixture was centrifuged and the supernatant fluid withdrawn, 0.5 ml of this diluted plasma in small glass tubes of approximately 0.7 × 7 cm was dried from the frozen state by any of the standard methods using a high-vacuum pump are satisfactory. Dry nitrogen was run into the evacuated tubes containing the dried plasma, and the tubes were sealed in a blow pipe flame.

Testing of Fresh Plasma.—To 0.5 ml of diluted plasma were added four drops, about 0.2 ml, of a suspension of staphylococcus. The mixture was then incubated at 37° C for six hours and left at room temperature overnight, readings were taken at intervals. A comparison was made, with each of the selected strains, of (a) a dilute suspension from an overnight growth on an agar slope, (b) a similar suspension in tryptic digest broth, and (c) an overnight growth in digest broth.

TABLE I—Clotting Times with Fresh Rabbit Plasma

Dilution of Fresh Plasma	Organisms suspended in	Clotting Time with Strains					
		CN 49	CN 659	CN 70	CN 69	CN 384	CN 64
1/2	Saline from culture on agar slope	30 mins.	1 hr	5 hrs.	5 hrs.	Neg	Neg
	Broth from culture on agar slope	10 "	30 mins.	4 "	5 "	"	"
	Broth culture	20 "	10 "	3 "	4 "	"	"
1/6	Saline from culture on agar slope	30 mins.	1 hr	Neg	Neg	Neg	Neg
	Broth from culture on agar slope	10 "	1 "	3 hrs.	24 hrs	"	"
	Broth culture	10 "	10 mins.	5 "	24 "	"	"
1/18	Saline from culture on agar slope	10 mins.	2 hrs	Neg	Neg	Neg	Neg
	Broth from culture on agar slope	10 "	1 hr	5 hrs	5 hrs	"	"
	Broth culture	10 "	10 mins.	5 "	24 "	"	"

A suspension in broth or a broth culture is satisfactory, whereas suspension in saline is ineffective with higher dilutions of plasma, as shown by Fisk (1940).

It was thought that there might be differences in the coagulability of different rabbit plasmas, but there was no significant difference in the clotting time when the plasma of 18 normal rabbits was tested against the six strains of staphylococcus.

Testing of Dried Plasma.—For use in the test, dried plasma was dissolved in a volume of distilled water equal to the volume of the plasma before drying. Table II shows the clotting time of three dried rabbit plasmas tested against the six selected strains. The dried plasma was dissolved in 0.5 ml of distilled water and tested against a broth suspension of an overnight growth of staphylococcus on an agar slope. It can be seen that the dried plasma is just as effective as fresh undried plasma. So far the dried product has shown no deterioration over a period of twelve months, and it is possible that it will be stable for a much longer period.

TABLE II—Clotting Times with Dried Rabbit Plasma

	3	30 mins	2 hrs.	4 "	4 "	"	"

Slide Test for Coagulase-positive Staphylococci.—Since the original observation of Much (1908) that coagulase positive staphylococci are immediately clumped by plasma, a slide test has been used extensively in some laboratories. Berger (1943) found that natural agglutinins are present in some samples of normal rabbit serum. In order to "obviate this source of false positive results" he used a fibrinogen solution, which when stored in the ice chest could be used for "at least four weeks." The dried plasma was found to be as suitable as the fresh plasma when used in the slide test. However, a number of strains of staphylococcus which were coagulase-positive with the tube test failed to give a slide test with either fresh or dried rabbit plasma.

SUMMARY

Rabbit plasma may be conveniently dried for use in the staphylococcus coagulase test and is stable for at least twelve months.

Abortive Lobar Pneumonia after a Course of Sulphapyridine

The interest of this case lies in the occurrence of lobar pneumonia, in an abortive form, in an adult who had, three to five days before, had a full course of sulphapyridine therapy.

CASE HISTORY

A healthy man aged 36 fell ill with acute otitis media. He was put on full doses of sulphapyridine, and the otitis subsided uneventfully after four days. The sulphapyridine was stopped.

I had seen the patient on the morning of the sixth day. The same night I was called to him because of very severe pain in the right side of the chest. On examination he was obviously in great pain; there were no physical signs in the lungs, no temperature, no history of rigors or vomiting, and very little cough. The respirations were quickened, but this was thought to be due to the fact that deep breathing increased the intensity of the pain, which in addition was worse on movement. The possibility of lobar pneumonia was considered, but it was thought that the absence of temperature, the lack of physical signs, and the history rendered this improbable.

Expectant treatment was given—poultices and analgesics—and the comforting diagnosis of pleurodynia made. Next day the patient was much better. His appetite was normal, the pain was much less, and he felt very well. The condition had subsided to such an extent as to make a visit on the following day unnecessary. The patient seemed a perfectly fit man with a slight pain in the chest. On the next day but one he was again visited and found in the bathroom washing himself preparatory to going downstairs. To use his own expression, he was "champion." The chest was examined as a matter of routine and, to my astonishment, the right lower lobe presented the typical clinical features of consolidation. The signs were those of lobar pneumonia on the second to fourth day of illness. It was only then that one was able to inform the patient of the diagnosis and, after belief had succeeded scepticism, his return to bed was effected. Convalescence was uneventful.

COMMENT

This case is differentiated from one of abortive pneumonia (maladie de Weil) by the presence of well-marked physical signs which are said not to occur in the latter condition. It is thought that the case may be of interest as adding weight to the suggestion that sulphapyridine or similar drugs should be given prophylactically in conditions in which pneumonia is likely to be a complication, and also because it suggests that patients who have been on a full course of sulphonamide therapy should not be released from medical observation until a full routine clinical examination has been made.

Reviews

THE MEDICAL ANNUAL

Medical Annual, 1944. Edited by Sir Henry Tidy, M.D., F.R.C.P.; and A. Rendle Short, M.D., F.R.C.S. Sixty-second year. (Pp. 404; illustrated, 25s., postage 7d.) Bristol: John Wright and Sons, Ltd.; London: Simpkin Marshall (1941) Ltd.

To look back on the medical events of the past year is a wholesome form of postgraduate education, and for years many doctors have found one of the best ways of doing this is to subscribe to the *Medical Annual*, the 1944 edition of which has now been published. It still appears between the evergreen covers, and as usual presents its information in alphabetical order, the first article being "Abdomen, Injuries of," and the last "Yellow Fever." The editors present their familiar survey as an introduction, and the advertisers present their wares in as attractive a manner as possible.

To review such a work adequately would be to list the entries from A to Y and to say after each one, "This is very good." Although the editors observe of the sulphonamides that "possibly in one or two directions the august nose has been put out of joint by its young rival, penicillin," there is no separate entry for penicillin, which seems to us to be a notable omission. What might be called a new department of medicine, known in America as geriatrics, is dealt with under the heading of "Ageing." By reason of the changing distribution of age groups this subject will attract growing attention, and in the meanwhile we might agree with the author's conclusion that "the practical upshot of the problem, as we see it at present, is that certain advantages may accrue from the employment of experienced and well-preserved elders." Though there is apparent anxiety to preserve the elderly, there does not seem to be the same concern in preserving the young, as on a quick glance through we can find no reference to the important problem of infant mortality. The usefulness of the volume as a whole would be much improved by a yearly article under the heading of "Vital Statistics." One disease of special interest—namely, infective hepatitis—is dealt with in the most admirably illustrated article by Col. William S. Middleton, consultant physician to the United States Army in the European Theatre of Operations: so far as we know this is the first time that any contributor from outside the British profession has joined the distinguished team which makes the *Medical Annual* what it is.

ALCOHOL ADDICTION

Alcohol Addiction and Chronic Alcoholism. Edited on behalf of the Scientific Committee of the Research Council on Problems of Alcohol by E. M. Jellinek. Effects of Alcohol on the Individual: A Critical Exposition of Present Knowledge Volume I. (Pp 336. 26s. 6d. or 34.00.) New Haven: Yale University Press; London: Oxford University Press.

Anyone who has spent some months in the United States realizes that alcohol presents a problem there which is much more acute than in Britain. Many people here are content with beer or cider at meals, and drink only an occasional cocktail. In America the hotter weather and the increased tempo of life, which often begins with breakfast at 7 a.m., seem to demand more release about six in the evening than is given by mere cessation of work. So that more alcohol is drunk. When there are parties (and they are numerous) women drink a good deal too. There often appears to be a purpose about it, even a sense of obligation to drink much. One story of a farmer in Vermont on his way to town is told: a friend meeting him inquired, "Well, Tom, are you going to get drunk to-night?" "Ay," he replied, "and don't I dread it!" Hence alcohol has become in the U.S.A. a "medico-social issue," and a Research Council on Problems of Alcohol was organized in 1937. It includes names well known in this country, such as W. B. Cannon, A. J. Carlson, H. S. Gasser, and A. C. Ivy. The council decided to begin by preparing an analysis of existing literature on the problems of alcohol, and obtained funds for a study of the "Effects of Alcohol on the Individual" from the Carnegie Corporation of New York. The first contribution to this study has now appeared as Volume I on *Alcohol Addiction and Chronic Alcoholism*.

This book is edited by E. M. Jellinek, and has as its main contributors K. M. Bowman, who is professor of psychiatry

at the University of California, Norman Jolliffe, who studies nutrition, and the editor himself. The book has two parts, the first dealing with addiction and alcoholic mental disorders and a second concerned with chronic alcoholism and alcoholic encephalopathies in relation to nutrition. The worst feature of the book is that it is written in an unattractive style, which does not vary greatly in different parts. Sentences such as "These factors . . . are prominently discussed in propagandistically oriented writings" (p. 47), or "The experimental study of factors determining inherent tolerance offers a first approximation to the systematic exploration of the etiology of addiction" (p. 46) are fair examples of a prose which has the distracting quality of a toothache, so that it is difficult to take in what one has read. A close runner-up as the worst feature of the book is the psychiatric or psychological jargon with which it abounds. The reader must contend with "acute alcoholic hallucinosis," "amnesic polyneuritic psychosis," "exogenic syndrome," and the like—technical terms which make the reading possible only to specialists. The trouble is that it is impossible at present to make any connected story out of the available facts. In the section on nutrition one looks in vain for those beautiful experiments done by Sebrell—to them A. P. Herbert devoted a page of *Punch*—in which it was observed that rats eating a diet deficient in vitamin B₁ were symptom-free for a longer time when whisky was included in their food. Despite all attempts to explain it away, the result stands unshaken.

As a collection and examination of the literature this book undoubtedly has much value for the specialist, but it is evident that not much of general interest is yet known of this subject.

MEDICAL PROBLEMS OF FLYING

Principles and Practice of Aviation Medicine. By Harry G. Armstrong, M.D., F.A.C.P., Second edition. (Pp. 514; illustrated, 36s.) London: Baillière, Tindall and Cox. 1943.

Physiology in Aviation. By Chalmers L. Gemmill, B.S., M.D., (Pp 129; illustrated, 52.00 prepaid or 11s.) Springfield and Baltimore: Charles C. Thomas; London: Baillière, Tindall and Cox.

The first edition of Col. Armstrong's valuable textbook appeared most opportunely in time for the outbreak of hostilities in 1939, thirteen years after Bauer's smaller textbook *Aviation Medicine*. Its circulation was therefore enormous, since the need for it was great, and it soon formed the basis of learning for many Air Force medical officers. It was admirable for the purpose, and the careful expositions of the underlying human physiology were most valuable to the doctor who had left his civilian practice to follow a surprisingly new form of medicine. After its appearance, aviation medicine in the Services made enormous strides, and sections of the book became open to serious criticism. The second edition has appeared to meet an increasing demand, but, as the author freely admits, it has not been possible to alter the text so as to bring it up to date because he cannot use any of the material which he has at his finger-tips, for it is still considered secret or confidential. He has been able to recast some sections—for instance, that dealing with neuroses—so as to bring them into general line with present thought, and has made additions, as in the section on equilibrium. Nevertheless the bulk of the book remains unchanged, and many chapters, particularly those dealing with high-altitude physiology, oxygen equipment, the physical and psychological standards of air-crew selection, air-sickness, and chronic altitude sickness, will need revision as soon as security and the author's important Service duties permit. This will no doubt lead to an edition which will re-establish the book as the standard text in aviation medicine. In the meantime the second edition is a very valuable stop-gap, which will implement the serving doctor's practical experience.

The excellent short text of *Physiology in Aviation* is based on a course of lectures given by Cmdr. Gemmill at the School of Aviation Medicine in Pensacola. If the Air Force medical officer is to understand the medical problems of modern flying he must have a sound basis of the physiology of respiration and circulation. Cmdr. Gemmill explains in seven short chapters the physical properties of gases and the normal physiology of gaseous exchange before he deals with the effects of low pressure and of anoxia. He then gives a simple account of the physiology of the circulation before he explains the effects of acceleration. Then he deals very briefly with the physiology

IMPROVED CONTROL

IN DIABETES MELLITUS

Globin Insulin (with Zinc), 'Wellcome' brand, is a clear solution with an action which is quick in onset and moderately prolonged in duration. This feature gives improved control of the blood-sugar level in many cases of diabetes, enabling them to be satisfactorily maintained on a single daily injection.

'SONERYL'

TRADE MARK

BRAND

butobarbitone

for insomnia and anxiety states

At the present time the practitioner is faced with an increasing number of patients suffering from insomnia and anxiety states. These cases are adequately treated by the discriminate prescribing of 'Soneryl.' Being rapidly eliminated, this product seldom gives rise to post-hypnotic dullness, and so enables the patient to go about his work refreshed in mind and body. 'Soneryl' may be taken over lengthy periods without the danger of habit formation.

SOCIAL INSURANCE

The Minister of Reconstruction presented to Parliament last week two documents which will rank of first importance in the social history of Great Britain.¹ The first set forth the Government plans for a comprehensive scheme of social insurance—a “mosaic of detail,” covering sickness, invalidity, and unemployment benefits, retirement pensions, and family allowances. Family allowances, by the way, are to be met wholly out of taxation, and therefore do not strictly come within social insurance. In the other cases the tripartite system of contributions by the insured, his employer (if he has one), and the Exchequer holds good. The second document outlined proposals for an industrial injury insurance scheme to replace the present system of workmen's compensation. Workmen's compensation, established nearly fifty years ago, was the pioneer scheme of social security in this country. It is now to be lifted clean out of the employer-versus-employee arena, which has often proved litigious, made into a social service, and placed, like the other benefits, under a Ministry of Social Insurance.

As in the proposed National Health Service, so in this wider territory the governing principle is comprehensive-ness. There is no variation or shadow of turning from the 100% inclusion. All ages, all economic groups, all occupations—the leader at the Bar and the woman who sweeps his chambers—all are roped into compulsory insurance, thereby far more than doubling the present number of insured persons. Provision extends from the nursery, by way of maternity benefit and children's allowances, to the grave, by way of a death grant. It is designed to guard against “every one of the main attacks which economic ill fortune can launch against individual well-being and peace of mind.” All persons will pay a single weekly contribution for all benefits by means of one stamp on one card.

In both these documents the Government has largely drawn upon the proposals put forward by Sir William Beveridge in November, 1942. In some respects it has gone further than the Beveridge plan; in others not so far. It has been more generous to the elderly, more parsimonious to the young. Retirement pensions start at some shillings a week higher under the Government scheme, and, on the other hand, children's allowances are on a more meagre scale. The Beveridge scheme would have made £110 million a year available for cash allowances in respect of children. The Government, believing that a substantial part of the benefit should be in kind, makes only £69 million available in cash, but states that school meals and milk services will be so extended that when they have reached their full development the cost will not be

much below the total for cash allowances. Before these services reach such full development, however, much time may elapse; there are large parts of the country where the services do not exist, and in any event they are only for school-children, or, rather, for children while attending school. Unless this provision is quickened the nutrition of children, especially in homes where there is sickness or misfortune, may not be improved to anything like the extent that advocates of family allowances had hoped. The dilemma of the social planner is, of course, to bestow benefits without encouraging the idler, the spendthrift, and the malingerer, and without sapping the initiative of the country's manhood: the free gift of *panem et circenses* to the Roman populace was a policy characteristic of the decline and not of the rise of the Roman Empire. It is held by the Government to be psychologically unwise to make sickness benefit of unlimited duration, and no one can complain that a benefit covering three years of continuous sickness is ungenerous. But the chronic invalid at the end of three years, returning to the lower scale of insurance benefit, is likely to be in the same or greater need of assistance. Indeed, in such cases it is not a question of a few shillings less or more, but of individual care, perhaps of institutional care, of which nothing is said in this White Paper. The Beveridge plan, though it dismissed the approved society system as such from the administration of compulsory cash benefits for sickness, allowed a possible field for friendly societies as agents. The Government bangs the door upon approved societies altogether. The Ministry of Social Insurance will itself administer sick pay. The approved societies are powerful bodies, and already the sharpening of battle axes is to be heard. The medical profession has had to criticize approved societies, but it seems a pity that their special experience in administration should go to waste. The friendly societies have maintained a sense of fellowship and a human touch which has been a distinctive contribution to social progress.

In the proposals to supersede workmen's compensation more marked departures have been made from the Beveridge scheme. Sir William Beveridge was less inspired in this part of his plan than in others. His proposals were unduly complicated, probably because he tried to reconcile the many different views put before his committee. The existing scheme finds no defender; it has proved costly and often contentious, and has not always brought to the workman the promised security. The Government has not accepted, among other Beveridge proposals, the recommendation to relate industrial pensions for long-term disability to pre-accident earnings. It has abandoned the principle of compensation according to earning capacity; compensation will be given according to the extent to which the workman has suffered disablement by comparison with a normal healthy person of the same age and sex. Thus the casualties of industry will be on the same footing as the casualties of war, and from that point of view there is something to be said for the proposal to entrust the medical assessment to the medical boards of the Ministry of Pensions, with the right of appeal to a special tribunal consisting of two medical practitioners and a chairman. The British Medical Association, in evidence which it submitted in 1939 to the Royal Commission on

¹ Cmd. 6550 and 6551. London: H.M. Stationery Office.

Workmen's Compensation, urged the replacement of the office of medical referee by the setting up of such a board consisting of three practitioners. The Association, of course, could not foresee at that time the removal of workmen's compensation from the law of employer's liability, and it directed its attention to the remedying of certain features which had proved objectionable in experience. One of these was the "lump-sum" payment, which it held responsible for the prolongation of disability in many cases. Under the new Government proposals the "lump-sum" payment, except in some cases of minor disability, will not replace pension. A matter on which the Association laid special stress five years ago was the need for rehabilitation centres. The most baffling problem in connexion with industrial disability is that of "light work," a term which has never been legally defined, while the medical side of the problem itself has never been fully explored. The Association suggested that the situation could be met by the establishment of rehabilitation units, and it devoted more than half its memorandum of evidence to this question. The new White Paper makes very scant reference to that side of the subject. Rehabilitation has been, if not ignored, at least overshadowed by the cash register. It is simply stated that it will be provided as part of the general medical and post-hospital services provided by Health Departments and by the Ministry of Labour and National Service, that there should be close contact between these Departments and the new Ministry of Social Insurance, and that there will be an obligation on the workman to undergo training. But one misses the accent on restoration and the improvement and promotion of health. Allowances and pensions, after all, are the flags of defeat. The ideal to aim at is a state of affairs in which they are never thought about.

It is evident that both these White Papers are, in a sense, interim documents. A bold map has been drawn, but many topographical details remain to be filled in. Nothing is said about the all-important role which the doctor will take as the guardian of many of these benefits. The integrity of the scheme so far as sickness, invalidity, and industrial injury benefits are concerned will depend upon his certification. No doubt it has been the anticipation of this which has inspired recent official and semi-official warnings about false and misleading certificates. It is acknowledged that the serious difficulty is to secure effective control over the payment of benefit, especially in the case of sickness benefit for persons working on their own account. Several problems in this field call for further consideration. The scheme may be modified by Parliamentary debate and public discussion, but from the "firm proposals," as they are called, the Government is not likely to be deflected—namely, the principle of comprehensiveness and of unification in a single administrative framework. After the usual acclamation which greets a White Paper dissentient voices are being heard. Some are disturbed at the cost of the proposals, which will place new burdens on employers and taxpayers. If the entire scheme were in force next year it would cost £673 million, including £148 million for the enlarged National Health Service, which is some £250 million more than the present expenditure, and of that extra amount £78 million would come

out of rates and taxes. Others—or perhaps the same people—fear that the British qualities of independence and self-help will deteriorate. They say with Hecate to the witches of *Macbeth*: "Security is mortal's chiefest enemy." But the same thing was said when National Health Insurance was born, and no doubt when the Poor Law, the oldest of our social services, and now in its final stages of liquidation, came into existence. Such critics, who are probably mostly of his party, might be reminded of Disraeli's dictum that individual security is the necessary foundation of national well-being. Those who can sense the coming time feel that these social security plans are as necessary in peace as victory in war, and that without them the fruits of victory will be soured. So long as security is looked upon as a right which the citizen has to deserve and earn, and so long as he makes an insurance payment for it, then such plans, fulfilled, may act as a stimulus and not as a deterrent to the effort this country will have to put forth in the years to come.

TREATMENT OF CEREBROSPINAL FEVER

A report now published by the Department of Health for Scotland¹ entitled "Sulphonamides in the Treatment of Meningococcal Meningitis" reveals that a systematic study of this disease has been in progress in Scotland for some years past. All cases admitted during the years 1936 to 1941 inclusive to the infectious fever hospitals of Edinburgh, Glasgow, Dundee, and Lanark County have been made the subject of a detailed return, and particulars are thus available of 2,223 cases, representing about 40% of total cases notified in Scotland during this six-year period. The actual form used is not reproduced in this report, but the items of information required are mentioned, and they are comprehensive enough to enable the effect of different forms of treatment to be analysed and assessed from several points of view. This report is in a condensed form and intended only as a preliminary survey; greater detail is promised in a later publication. It begins by reviewing the history of cerebrospinal fever in Scotland during the past forty years. In frequency it has shown four peak years—1907 (2,115 cases); 1915 (409); 1931 (409); and 1940 (2,580). Each has been followed by a slow decline, the normal inter-epidemic level being reached only after three years. There has also been a rise in the inter-epidemic level from an annual average of 70 cases in 1911–14 to over 200 in 1929–39. Brief particulars are given of seasonal and age distribution: a notable difference between these and the English figures quoted by Beeson and Westerman² is that 66% of the patients in Scotland were under 15 years old, whereas the corresponding English figure is only 45.5%.

The number of cases in the 6 years covered by the report were successively 99, 120, 110, 100, 1,005, and 763; thus the great majority were those occurring in the first winter of the war and in the succeeding epidemic season. The over-all fatality rate was 16.7%, in contrast to a rate

¹ Report to the Scientific Advisory Committee, Department of Health for Scotland. Edinburgh: H.M. Stationery Office, 1944. (4d.)

² *British Medical Journal*, 1943, 1, 497.

of over 50% in the pre-sulphonamide era. The mortality at different ages shows the same general distribution both in the past and in the period under study, with maxima in infancy and in the highest age groups. The fatality rate among cases receiving different forms of treatment affords the main interest of the report, and may be stated briefly as follows, omitting deductions given in the tables for patients dying less than 24 hours after admission. Among 199 cases treated with "serum or antitoxin" alone the fatality rate was 51.7%. There is nothing surprising in this, but a rate of 31.2% among 250 cases treated with both serum and antitoxin and sulphonamides is unexpected. Reasons are given for concluding that these cases were not exceptionally severe, and inadequate dosage of the drug is not held accountable; the suggestion is made that the effect on the meninges of intrathecal serum injection may be responsible. Among cases treated with sulphonamides alone there are four categories, the numbers and fatality rates being as follows: sulphapyridine 1,468 (17.17%), sulphanilamide 128 (9.3%), sulphathiazole 75 (14.6%), and miscellaneous sulphonamides 91 (20.9%). It is unfortunate that these numbers are so unequal, and in particular that the cases treated with sulphanilamide were not more numerous, since, contrary to commonly accepted belief, this drug is shown to have been the most effective. It is said to have been used chiefly at one centre, which suggests that other non-specific factors in treatment may have influenced the results, but throughout the period of the study, which excludes any likelihood that a mild series of cases was treated in this way. It is clearly desirable that further comparative studies should be made on these lines, in which sulphanilamide is used in the same proportion of cases as are other now more popular drugs. These observations have at least reopened this question, and suggest the inadvisability of assessing the relative merits of closely similar drugs on any but an adequate statistical basis. In very many instances clinical impressions are in fact responsible for the choice of particular sulphonamides for various specific purposes, no adequate comparisons on which a firm judgment can be based having ever been made.

The sole demonstrated drawback of sulphanilamide treatment in cerebrospinal fever is a greater frequency of pneumonia as a complication; if the lung infection was pneumococcal (a point on which information is not available) this is to be expected. The fatality rate in sulphapyridine-treated cases appears unduly high, and since dosage was in general adequate it is concluded that the disease in Scotland has been of a more virulent nature than in the South of England, where treatment with this drug has given better results. An analysis of therapeutic effect in relation to the scale of dosage of sulphapyridine yields some peculiar findings. In infants the fatality rate declines as dosage increases, but in the 2-4 years group the lower doses gave the best results, and over 15 years a medium dosage. It is therefore hardly surprising that the authors of the report are disinclined to be dogmatic about optimum dosage. Presumably this study will be continued, and both in Scotland and elsewhere it is to be hoped that available clinical material may be used in a deliberate endeavour to define optimum lines of treatment.

VITAMIN B₁ AND THE HEART

In a recent letter to the *Journal*¹ Dr. J. Drummond has affirmed the value of vitamin B₁ in high dosage as a "cardiac tonic" in heart failure and auricular fibrillation. On theoretical grounds benefit might well be expected, as we are reminded by a recent review.² Vitamin B₁, or thiamin, is essential for the efficient combustion of the carbohydrate which provides energy for the metabolism of tissues, and the effects of B₁ deficiency are most likely to appear in organs continuously at work—namely, the brain, nervous system, heart, and kidneys.³ In the cardiovascular system the main features are right ventricular failure with systemic venous congestion and oedema, capillary pulsation, and a low diastolic pressure. Usually there is a striking absence of orthopnoea, but cases may occur in which left-sided failure is present with dyspnoea and orthopnoea.⁴ The cardiovascular symptoms may be associated with polyneuritis or other consequences of vitamin deficiencies. Electrocardiographic changes attributed to vitamin-B₁ deficiency have not always been consistent. The heart in beriberi shows typically, however, an inversion of T waves and a low amplitude in all complexes.⁵ In human volunteers with induced thiamin deficiency Williams⁶ observed a similar diminution in the amplitude of all waves, particularly the T waves. A comparable condition has been produced in pigs maintained on a thiamin-deficient diet.⁷ Clinically some of these animals developed cyanosis, dyspnoea, and bradycardia, these signs being accompanied by electrocardiographic abnormalities. Pathologically there was cardiac dilatation without hypertrophy, and the myocardium showed focal and diffuse necroses.⁸

It is one thing, however, to agree that deficiency of vitamin B₁ may lead to heart failure, as in the classical form of wet beriberi, and quite another to claim that deficiency of vitamin B₁ plays a significant part in cardiac failure as seen in this country. There is no evidence that vitamin-B₁ deficiency is present to any appreciable extent in the normal population of this country, and our wartime diet is more than adequate in this respect. Nevertheless a "conditioned deficiency" of vitamin B₁ might occur in heart failure as a result of a long-restricted diet, deficient assimilation of food, or an increased need. The intake of food may be inadequate, assimilation may be deficient as the result of systemic venous congestion, and the requirements of B₁ are increased by the considerable rise in the metabolic rate which occurs in many persons with congestive heart failure.⁹ It is possible, therefore, that a thiamin deficiency might occur as a complication of chronic heart disease. Although satisfactory biochemical methods of assessing thiamin deficiency are now available, there is at present no evidence that such a deficiency is common in heart failure. Finally, it is conceivable that vitamin B₁ might have a pharmacological action in heart failure which was quite independent of its action as a vitamin, in the same way that nicotinic acid (but not nicotinamide) relieves angina, migraine, vertigo, and neuralgia. The proof of the pudding must be in the eating, and it is probable that the majority of cardiologists would not agree with Dr. Drummond in his eulogy of vitamin B₁. The few patients in whom it is effective usually give a history of long-standing alcoholism and gross dietary deficiency.

They are, in fact, technically suffering from secondary beriberi. In 1939 Arthur Hurst¹⁰ reminded us that R. T. Williamson of Manchester described this type of heart failure many years ago and advised testing the tendon reflexes in obscure cases of heart failure. With the exception of beriberi and the alcoholic heart, it is doubtful whether vitamin B₁ has an established place in cardiac therapeutics.

THE MAKING OF BOOKS

Mr. Stanley Unwin's discourse at the Royal Institution on *Publishing in Peace and War*¹¹ will give pleasure and pain to all who love books. The pleasure will come from the pages which describe book production, because most readers will learn something new to them; the pain will be inflicted by that part of the pamphlet which discusses the state of book production now. The facts are these. Owing to wartime conditions the demand for books, not merely escapist fiction but solid textbooks and classical works, is greater than it has ever been, but the supply is wholly inadequate. We might add—scientific periodicals did not come within the scope of Mr. Unwin's lecture—that many valuable research papers accepted by editors are on a waiting list which grows every day longer, and that at least one director of a medical research department proposes to submit papers in future to American scientific journals. Mr. Unwin speaks with not unnatural bitterness of the attitude of some Ministers and some civil servants. Some Ministers may be illiterate or at least have that contempt for books which is supposed to characterize practical men—no doubt the practical men who, in Huxley's phrase, practise the errors of their forefathers—but most civil servants have at least shown in examination rooms a knowledge of the contents of many books. Perhaps the cynic would say that those who have books of their own and access to good libraries do not lose much sleep over the mental starvation of "the public." A more charitable explanation would be that decisions were taken at a time when the wiser heads among administrators were preoccupied with matters of life and death. Mr. Unwin notes that the allocation of paper for books in 1945 is less than 22,000 tons, a little more than one-fifth of the allocation to H.M. Stationery Office. One grows a little weary of the comic tales of civil service lust for useless forms; but many of them are true, and anybody who has worked in a temporary Government Department could give examples of waste. Very often there is a good defence in theory—or, shall we say?—on paper. Unless a complete documentation survives (the argument runs) it will be impossible to write a history of "the Department," and so, in the next war, mistakes will be repeated.

In America," Mr. Unwin writes, "the cult of the best-seller has reached such a pitch that a scholarly work stands little chance of acceptance by a commercial publisher unless it has mass appeal. Over here there is still far more long term non-commercial and prestige publishing than is usually credited, and this is as it should be. But if continuously discouraged it will disappear, and unfortunately in recent times discouragement has come to it from all sides."

It is surely true that in America assistance in the publication of scholarly works can be obtained at least as easily as here, and that the production of serious scholarly periodicals is great. The war has brought the scholars of America and Great Britain into still closer contact than in 1939, it may easily happen that our younger men will look to the other side of the Atlantic for vehicles of publication; from the point of view of making their results known to the learned world nothing will be lost. Still, one might regret this on sentimental grounds.

A WINDOW ON SCOTTISH SLUMS

For many years to come stories of the wartime evacuation from Glasgow and Edinburgh and their outflow north and south will be told in the burghs, villages, and glens of Scotland. The authentic story of the woman quartered in a cottage on a Highland estate. "Ma weans were told they were to sleep in the King's bedroom. This'll no do." The children who, after a good dinner, were confronted with a plain tea with warm scones. "We're no takin' that. You're paid by Government. We're for ham and eggs." And as a sidelight on the habits of some, the mother's remark. "Johnnie, don't use the lady's carpet, use the surround." The publication early in 1943 of *Our Towns: A Close-up* administered a wholesome shock to the social conscience of England, and now a group of Scottish women—the editorial committee of the Scottish Women's Group of Public Welfare—have done the same for their own country.¹ They tell the story of the 180,000 children and their mothers who have been packed away in 500 trains from Scottish towns to rural places during the war. For the most part it is a melancholy tale. Complaint is made that many of the mothers had not the most elementary knowledge of plain and simple feeding. But the bitterest complaint concerned the uncleanness of the children. In one village which received its entire contingent from a slum school 50% were said to have dirty heads, 30% impetigo, and 20% to be incontinent in their habits. Drastic action was taken in this case by officials and housewives, with a resulting fall of four feet in the local reservoir and a dearth of disinfectants at the chemist's shop. As for enuresis, it is impossible to estimate in what proportion of cases this was temporary and brought on by excitement or nervousness and perhaps by the coldness of country houses, but many of the children seemed never to have been trained to make use of toilet conveniences. On the other hand, the strangeness and loneliness of the new environment to people who have been living 188 to the acre has to be remembered. Many of them had been transported from Glasgow slums to Highland shooting lodges, and the loneliness was too much for them. In one mansion several families were allotted a room each, but in the morning all the twenty-five women and children were found huddled in two rooms and they left within ten days. Amid so much filth and recklessness two very human touches stand out—the unity of the family and the fear of an institution. No Government circular was ever more tightly grappled to the breast than the official promise not to break up the family. They must literally touch one another at night. A bus laden with weary mothers and children drew up at the entrance to a huge square mansion where the eager kind hostess awaited her guests with every comfort. "No' me! No' me! I'm no' gaun into an institution!" they cried, and wild horses would not have dragged them up the steps. However social reconstruction is to come about, it is evident that the integrity of the family is a factor to be placed in the forefront.

The Committee of Privy Council for Medical Research has appointed Dr. Alan Nigel Drury, F.R.S. (Director of the Lister Institute of Preventive Medicine) and Prof. James Calvert Spence, M.D., F.R.C.P., of Newcastle-upon-Tyne to be members of the Medical Research Council from Oct. 1, 1944.

Fracture-dislocation of Talus

SIR,—In his article on fracture-dislocation of the talus (*Journal*, Sept. 16, p. 372) Squad. Ldr. James draws attention to an unusual injury which is of particular importance to the Royal Air Force because it occurs with relative frequency in pilots and air-crews, and because it is potentially one of the most crippling of all lower-limb injuries. In the orthopaedic service of the Royal Air Force we have a larger series of cases than has ever been recorded in this or any other country, and careful analysis has led us to very different conclusions from those of Squad. Ldr. James. He writes: "Closed reduction of the dislocated body if at all feasible is extremely difficult. Reduction therefore, if attempted, should advisedly be open." On the contrary, manipulative reduction, which is occasionally very easy, should always be attempted with determination before embarking on the still more difficult and still more hazardous procedure of operative reduction. One of the major problems in the treatment of this injury is loss of blood supply to the body of the bone, and it is obvious that operative dissection and stripping of soft tissues, which may still further reduce the blood supply, is to be avoided if possible.

Again he writes: "Talectomy.—A comparatively satisfactory result may be obtained if it is performed with care and attention to detail. . . . The depreciation of this operation is in large measure due to inadequate surgical technique." This has not been our experience. No matter how carefully and skilfully the talus has been removed the results have been unsatisfactory. After this operation it is seldom possible for a patient to walk 10 or 15 miles, to run, or to jump from a height. Moreover, the aching pain which develops after exercise steadily increases as the years go by, and even when the early result seems excellent it may be almost impossible to walk after five years. For these reasons nearly every case where there had been a previous talectomy has been treated in the Service by tibio-calcaneal fusion. As Squad Ldr. James points out, this operation "is still on trial"; but it has been done long enough for one pilot to write last week from the Far East, where, two years after tibio-calcaneal fusion, he is engaged on full flying duties: "Sir, it is wonderful; my gait is absolutely natural. May I sincerely thank you."

In his final paragraph Squad. Ldr. James writes: "Arthrodesis.—This should be the treatment of choice. It is needless to prolong treatment by employing reduction first. Arthrodesis should be the only operation." As we have said, arthrodesis of both ankle and subtalar joints (or tibio-calcaneal fusion after talectomy) gives surprisingly good results, but it is far from true to suggest that this should be the only treatment, and that it is useless to try preliminary reduction. A number of patients whose fracture-dislocations have been reduced have regained a completely normal range of movement and a foot which from every other point of view is indistinguishable from normal. It cannot be denied that a normal foot is better than an arthrodesed foot.—We are, etc.,

Artificial Respiration

SIR,—The recent discussions in the *Journal* concerning the most efficient method of artificial respiration and Dr. Tingley's article on the rate thereof prompt me to write in order to emphasize a fundamental point apparently neglected by lecturers and instructors in first aid—the importance of maintaining an efficient airway in the patient, without which any method of artificial respiration is valueless.

As a divisional surgeon to the Metropolitan Police it has been my duty to attend a considerable number of cases of asphyxia—mainly suicidal and the result of coal-gas poisoning. On my arrival I almost always find the victim in the open air receiving artificial respiration by Schäfer's method; but I cannot recall a single occasion on which I was satisfied that there was

any tidal exchange of air. Frequently the asphyxial element had caused such a degree of respiratory obstruction that efforts at artificial respiration have actually progressively reduced the residual air in the lungs. Perhaps the practical demonstrations which first-aiders have had, being, as they would be, on live and co-operative subjects, has misled them into thinking that artificial respiration is equally easy on the flaccid asphyxiated subject. In this respect I blame the Schäfer method (as opposed to the Silvester), as it assumes that because the patient is prone the tongue must fall forward and the airway is therefore assured.

I suggest that in teaching first aid: (1) Every possible emphasis should be laid on the importance of an adequate airway. Every breath should be heard, in both inspiration and expiration; and all other details of the "drill" such as timing and position of patient are secondary to this. (2) Every resuscitation outfit (such as the "Novox" apparatus carried in most accident ambulances) should have as an addition a set of pharyngeal airways of varied sizes of the type known to anaesthetists as Guedel's. These are all rubber and atraumatic (one can, in fact, be worn by a conscious patient without gagging), and five minutes' instruction would make an ambulance attendant competent to fit one of the appropriate size. The O/CO₂ mixture could then be administered or artificial respiration carried out with the confidence that an efficient airway had been provided and would require no supervision for its maintenance.—I am, etc.,

Ilford, Essex.

The Metric System and Medicine

SIR,—One of the stumbling-blocks, possibly the largest, to the general use of the metric system in prescribing is the reluctance of examining boards to insist on the use of metric dosage by examinees. The personal responsibility for this lies, therefore, with the clinical teachers. Their reluctance to prescribe in terms of the metric system is based on the fact that they were brought up on imperial weights and measures; many of us would be hard put to supply a metric equivalent with any promptitude. A similar position arose in like manner during the change-over from the old to the new anatomical terminology. This inertia, though very human, is deplorable. Its early eradication can be achieved only by compulsion on the part of the examining bodies.

Although in many instances the metric dose is just as easy to learn as the imperial equivalent, this is by no means always the case. The *B.P.* frowns on the milligramme and uses fractions of a gramme; this method is consequently followed in most of the textbooks. One example will suffice to show why the other system is still so much in favour: physostigmine salicylate, 1/100 to 1/50 grain—0.0006 to 0.0012 g. It may be argued that it is perfectly simple to convert the latter to milligrammes; this is true, but the student's labours are unnecessarily increased if, whilst learning his posology, he has also to carry out a conversion with each metric dose. Examiners will much prefer to hear of milligrammes rather than fractions of a gramme. It would be a great help to the student if textbooks were to give metric doses in the manner that they are used in the wards, leaving the less easily memorized *B.P.* decimals in brackets.—I am, etc.,

London, W.1.

A. H. DOUTHWAITE.

SIR,—I fully agree with the opinions and reasons already expressed on the above topic. To my mind the ideal time has arrived to change over and prescribe in the metric system.
